**Abstract** Bacteria and fungi in shared environments compete with one another for common substrates, and this competition typically involves microbially-produced small molecules. An investigation of one shared environmental niche, the carton material of the Formosan subterranean termite *Coptotermes formosanus*, identified the participants on one of these molecular exchanges. Molecular characterization of several termite-associated actinobacteria strains identified eleven known antimicrobial metabolites that may aid in protecting the *C. formosanus* colony from pathogenic fungal infections. One particular actinobacterial-derived small molecule, bafilomycin C1, elicited a strong chemical response from *Trichoderma harzianum*, a common soil saprophyte. Upon purification and structure elucidation, three major fungal metabolites were identified, t22-azaphilone, cryptenol, and homodimericin A. Both t22-azaphilone and homodimericin A are strongly upregulated, 123- and 38-fold, respectively, when exposed to bafilomycin C1, suggesting each play a role in defending *T. harzianum* from the toxic effect of bafilomycin C1.

**Keywords** *Trichoderma harzianum* · *Coptotermes formosanus* · Termite · Actinobacteria · Induction

## Introduction

Throughout their evolutionary history insects have engaged in mutually beneficial associations with microbes, including bacteria belonging to the chemically rich class of actinobacteria (Kaltenpoth 2009; Caldera et al. 2009; Crawford and Clardy 2011; Nett et al. 2009). In paradigmatic insect-bacteria systems the insect provides essential nutrients to the microbe and the bacteria provides a fitness advantage to the insect, such as an efficient chemical defense. Previous reports have illustrated the ability of actinobacteria associated with a variety of insects – beetles, ants, termites, and beewolf wasps – to protect the insect hosts from infections by ecologically relevant pathogens (Scott et al. 2008; Oh et al. 2009a, 2009b; Carr et al. 2012; Kaltenpoth et al. 2005; Kroiss et al. 2010). These studies exemplify the extraordinary potential of actinobacteria to produce structurally diverse antimicrobial agents, as illustrated by dentigerumycin, mycangimycin, and microtermolides (Oh et al. 2009a, 2009b; Carr et al. 2012). In contrast, studies on the molecular basis of the microbial pathogens' response to the actinobacterial defenses in an ecologically relevant framework are sparse.

The Formosan subterranean termite, *Coptotermes formosanus*, is an invasive and highly destructive insect, causing an estimated billion dollars per year in infrastructure damage and control cost in the United States alone (Lax and Osbrink 2003; Rusk and Su 2012). This termite species builds large underground nests that can contain more than one million individuals with foraging tunnels up to 100 m (King and Spink 1969; Su and Scheffrahn 1988). Due to the sheer size of these nests, they can be difficult to control via conventional soil insecticide treatments (Su and Scheffrahn 1998) and biological control attempts failed to eliminate field colonies (Culliney and Grace 2000; Grace 1997; Lax and Osbrink 2003;

Chouvenc et al. 2011). The core of the termite nest is filled with ‘carton material’, a sponge-like structure composed of nutritious chewed wood particles and fecal material that promotes the growth of mutualistic and opportunistic microbes, including parasites and pathogens (Chouvenc et al. 2013a). Preventing pathogenic fungi or other microbes from proliferating in the termite colony and on the fecal nest structure requires multiple mechanisms, including mutual- and self-grooming behavior by the termites to avoid bringing spores or fungal mycelia into the nest (Yanagawa et al. 2008; Chouvenc and Su 2010; Chouvenc and Su 2012). It also involves mutualistic relationships with beneficial microbes, especially the actinobacteria found within the carton material of the nests that significantly reduce the rate of infections by the fungal entomopathogen *Metarhizium anisopliae* (Chouvenc et al. 2013b).

We now report our recent efforts to evaluate the extracts from nine actinobacteria strains isolated from *C. formosanus* nests, that were previously identified to possess antifungal activity along with an initial examination of the fungal responses they induce (Chouvenc et al. 2013b). The current study led to the identification of eleven known biologically active bacteria-derived metabolites with antimicrobial activity. Interestingly, one *Streptomyces* metabolite induces the production of cryptenol (**1**), t22-azaphilone (**2**), and homodimericin A (**3**) in *Trichoderma harzianum* (Fig. 1), an ecologically relevant soil fungus that is known to take over the carton material of collapsed termite nests (Chouvenc et al. 2013a). The induction of these metabolites led to insights into the chemical interactions that are possibly occurring among microbes within the termite nest.

## Methods and Materials

**General Experimental Procedures** Optical rotations were measured on a JASCO P-2000 polarimeter, circular dichroism spectrum on a JASCO J-815, and UV spectra on an Amersham Biosciences Ultrospec 5300-pro UV/Visible spectrophotometer. NMR spectra were recorded with benzene or dimethylsulfoxide as internal standards ( $\delta_C$  128.06,  $\delta_H$  7.16 for  $C_6H_6$  and  $\delta_C$  39.52,  $\delta_H$  2.50 for DMSO) on a Varian Oxford 600 MHz spectrometer equipped with a 5 mm AutoX HCN triple resonance probe (600 and 150 MHz for  $^1H$  and  $^{13}C$  NMR, respectively), and on a Varian VNMRs (Varian NMR System) 500 MHz spectrometer equipped with a broadband Cold Probe (500 and 125 MHz for  $^1H$  and  $^{13}C$  NMR, respectively). LR-LCMS data were obtained using an Agilent 1200 series HPLC system equipped with a photo-diode array detector and a 6130 quadrupole mass spectrometer. HRESIMS was carried out using a Bruker Maxis Impact HD LC-q-TOF Mass Spectrometer equipped with an uHPLC system. HPLC

purifications were carried out using Agilent 1100 or 1200 series HPLC systems (Agilent Technologies) equipped with a photo-diode array detector. All solvents were of HPLC quality.

## Actinobacteria Isolation and Culture Conditions

Actinobacterial strains were isolated from the carton material of three colonies of the Formosan subterranean termite, *Coptotermes formosanus*, and the isolation protocol and characterization of these strains were reported previously (Chouvenc et al. 2013b). Nine of these actinobacterial strains – 7 *Streptomyces* and 2 *Kitasatospora* strains (Table 1) – were chosen for chemical investigations based on their interesting antimicrobial activity. *Streptomyces* sp. 4231 and *T. harzianum* WC13 (Genbank: KX694115) were both isolated from *C. formosanus* colonies, though were not found in the same colonies. *T. harzianum* WC13 was isolated from a dying *C. formosanus* colony and as the microbial community from the carton nest also collapsed, *T. harzianum* became the dominant saprophyte in a case of ecological succession (Chouvenc et al. 2013a). The actinobacterial strains were grown on 1/5 potato dextrose agar (DB Difco PDA) or 1/5 potato dextrose broth (DB Difco PDB) for 14 days. Solid agar cultures were kept at 30 °C in an incubator, while liquid cultures were grown in shakers maintained at 30 °C and 200 rpm.

**General Extraction and Isolation Procedure** The solid agar plates for the actinobacteria and *T. harzianum* cultures were exhaustively extracted (5 – one hour soaks) using 2:1 dichloromethane (DCM)—methanol (MeOH), to afford a crude extract. Liquid cultures were centrifuged and the spent media was passed through a column of XAD-16 resin. The resin was subsequently rinsed with deionized water, and washed with MeOH to elute the organic material. The MeOH wash was dried using rotary evaporator, yielding a crude extract. All crude extracts were fractionated by reverse-phase (RP) solid phase extraction (SPE) using a stepwise gradient solvent system of decreasing polarity, starting from 75% water ( $H_2O$ )/acetonitrile (ACN) to 100% DCM (five fractions, A-75%  $H_2O$ /ACN, B-50%  $H_2O$ /ACN, C-25%  $H_2O$ /ACN, D-100% ACN, and E-100% DCM). All SPE fractions were tested for antimicrobial activity against *Bacillus subtilis*, a gram-positive bacterium and five soil fungi known to opportunistically be associated with termite nests (Zoberi and Grace 1990; Chouvenc et al. 2013a), *T. harzianum*, *Beauveria bassiana*, *Penicillium* sp., *Aspergillus nomius*, and *Metarhizium anisopliae*. SPE fractions that exhibited activity against any of the microbes were subsequently purified on RP HPLC using one of the following Phenomenex semi-preparative columns, Kinetex biphenyl, Luna C18(2), Phenyl-Hexyl, or Hydro-RP, resulting in the purification of 11 known secondary metabolites (Table 1 and Figs S18-S29).

**Fig. 1** Structures of induced metabolites (1–3) by the soil saprophyte *T. harzianum* WC13 and the inducing agent (4) produced by termite-associated *Streptomyces* sp. 4231

**Purification of *Streptomyces* sp. 4231 Metabolites (Bafilomycins)** The D SPE fraction (100% ACN) from *Streptomyces* sp. 4231 grown on solid agar (1/5 PDA) induced pigment formation in *T. harzianum* and exhibited activity against *B. subtilis* and *A. nomius*, and consequently was subjected to further purification by RP HPLC. Further fractionation using a Phenomenex 4  $\mu$ m Luna C18(2) semi-preparative column, with a gradient from 50% ACN + 0.1% formic acid (FA)/H<sub>2</sub>O + 0.1% FA to 100% ACN + 0.1% FA over 25 min, yielded pure nataxazole, bafilomycin C1 (34.5 mg/L), B1, and D. The isolated material was confirmed to be bafilomycin C1 (4) via HRLCMS co-injections with authentic bafilomycin C1 (Enzo Scientific) (Fig. S25).

**Preparation of Conditioned Media (CM) for *Trichoderma harzianum* WC13 and Isolation of Induced Metabolites** The solid CM used in the induction studies was prepared following the previously reported method (Meyers et al. 2016). Briefly, the supernatant from liquid cultures of

*Streptomyces* sp. 4231 was combined with fresh media (2/5 PDA, 3% agar) and subsequently used to make CM plates (55 mL; 150  $\times$  15 mm Petri dish). These plates were then inoculated with refrigerated glycerol spore stocks (in 25% glycerol) from *T. harzianum* WC13 (Chouvenec et al. 2013a) and incubated at 30  $^{\circ}$ C for 4 days. At this time the plates were extracted and preliminarily fractionated following the method described above. The B SPE fraction (50% ACN/H<sub>2</sub>O) appeared to be enriched with induced yellow pigments and was thus subjected to further purification by RP HPLC. The pigments were purified using a Phenomenex Kinetex 5  $\mu$ m Biphenyl 100  $\text{\AA}$  semi-preparative column, with an isocratic gradient of 35% ACN + 0.1% FA/H<sub>2</sub>O + 0.1% FA, yielding 4.5 mg/L of culture media of cryptenol (1), 5.8 mg/L of culture media of t22-azaphilone (2), and 4.3 mg/L of culture media of homodimericin A (3). Induction levels for compounds 1, 2, and 3 were quantified from SPE fractions using extracted ion chromatograms (EIC) from LR-LCMS and determined to be 1.2-, 123-, and 38.7-fold increase in

production, respectively, when grown in the presence of 30  $\mu\text{M}$  bafilomycin C1 opposed to on 1/5 PDA for the same amount of time. The bafilomycin C1 containing solid agar plates were prepared by the addition of 1 mL of a 3 mM solution of bafilomycin C1 in DMSO to 1 L of freshly autoclaved 1/5 PDA media.

**Determining Relative Configuration of Cryptenol Using Acetonide Protection** An aliquot of cryptenol (**1**, 0.25 mg) was dissolved in 300  $\mu\text{L}$  of ethanol (EtOH) and treated with a small amount of 10% Pd/C and  $\text{H}_2$  (g) at room temperature (rt) for 4 h. at which point the reaction mixture was filtered through a glass plug containing celite. The reaction product was dried under vacuum, then dissolved in 0.6 mL ( $3 \times 0.2$  mL rinses) of dry DCM and transferred to a 10 mL pear flask that was previously charged with a small amount of activated 3 Å molecular sieves. Subsequently, the pear flask was treated with *p*-toluenesulfonic acid monohydrate (28  $\mu\text{g}$ , 0.15  $\mu\text{mol}$ ) in 0.2 mL of DCM and 2,2-dimethoxypropane (4  $\mu\text{L}$ ). The reaction mixture was stirred at room temperature for 16 h. At which point, 1 mL of saturated  $\text{NaHCO}_3$  (aq) was added and the mixture was extracted three times with DCM. The organic layer was dried using  $\text{Na}_2\text{SO}_4$ , filtered over celite, and dried under vacuum. The reaction product was then analyzed by  $^1\text{H}$  NMR using a 3 mm NMR tube (160  $\mu\text{L}$ ) in  $\text{C}_6\text{D}_6$ . The  $^1\text{H}$  NMR spectrum of the product was compared (Fig. S8) to two standards – threo-5,6-dodecanediol and erythro-5,6-dodecanediol – which were synthesized following the above procedure, assigning the relative stereoconfiguration as erythro.

spore stock (in 25% glycerol) was added to a 12 mL conical vial containing 10 mL of 1/5 PDA soft agar (55 °C, 0.75% agar). The mixture was vortexed and then poured over a plate of 1/5 PDA (25 mL; 100  $\times$  15 mm Petri dish). For the *B. subtilis* assays, 100  $\mu\text{L}$  of an overnight culture (in LB) was added to 10 mL of the soft agar, and was similarly vortexed and poured over a LB plate. Upon solidifying (~10 min), 1.5  $\mu\text{L}$  of each fraction or pure compound resuspended in 50% ACN/ $\text{H}_2\text{O}$  at 10 mg/mL, was spotted on the agar along with a solvent control, trying to minimize the surface diffusion. The inoculated assay plates were subsequently incubated at 30 °C for either 24 h or 72 h for the bacteria and fungi, respectively, at which point the zones of inhibition were measured and photographed. Determining the induction potential of fractions from *Streptomyces* sp. 4231 were assessed in a similar manner. See previous publication for detailed method (Mevers et al. 2016).

#### Determining Minimum Inhibition Concentration of T22-azaphilone on Solid Agar

A parent stock solution of freshly purified t22-azaphilone was prepared by dissolving an aliquot in DMSO at 15 mg/mL. A subsequent 1:10 dilution with 100% water yielded a 1.5 mg/mL solution in 10% DMSO (aq). This solution was then further diluted to form six working stock solutions with the final concentrations of 1.5, 0.75, 0.375, 0.190, 0.094, and 0.047 mg/mL. A 0.5 mL aliquot of each of these working solutions was added to a 50 mL conical vial containing 14.5 mL of 1/5 PDA (55 °C; 1.5% agar). The solutions were vortexed and dispensed in 1 mL aliquots per well into a 24-well sterile plate with each plate containing

three wells per concentration. In addition to the six concentrations of t22-azaphilone, three controls (two wells each) were plated on every plate – DMSO control (0.5 mL of 10% aqueous DMSO), negative control (1/5 PDA), and positive control (Penicillin-Streptomycin at 500 units and 0.5 mg/mL, respectively). Upon solidifying, each well was inoculated with 1  $\mu$ L of one of the bacterial suspension, *Streptomyces* sp. 4231 and 2083B and *Kitasatospora* sp. 2404, adjusted to  $1 \times 10^8$  cfu/mL (Wiegand et al. 2008). Plates were incubated for 48 h at 30 °C, at which point the plates were analyzed for bacterial growth and photographed.

## Results

**Identification of Antimicrobial Agents Produced by Termite-Associated Actinobacteria** Nine termite-associated actinobacterial strains – 7 *Streptomyces* and 2 *Kitasatospora* strains (Table 1) – were chosen for chemical investigations based on their antimicrobial activity, previously reported in Chouvenec et al. (2013b). These strains exhibited a range of inhibitory activity against both bacteria and ecologically relevant soil fungi in a binary competition assay. Upon extraction of either solid or liquid cultures from each strain and successive rounds of reverse-phase (RP) chromatography, eleven known metabolites were identified, including fungichromin, dactinomycin, 16-deethylindanomycin, streptonigrin, berninamycin A and B, bafilomycin B1, C and D, nataxazole, and mycotrienin (Table 1 and Figs S18–S29). Several new analogs of dactinomycin, berninamycin, and 16-deethylindanomycin were observed by mass spectrometry but were not isolated or characterized. Of this diverse group, only one of the metabolites (fungichromin) exhibited selective antifungal activity, four compounds (dactinomycin, berninamycin A and B, and streptonigrin) exhibited antibacterial activity against *B. subtilis*, and five metabolites (bafilomycin B1, C1 and D, mycotrienin, and 16-deethylindanomycin) exhibited both antibacterial and antifungal activity in spot-on-lawn assays, which agreed with previous literature on each of the secondary metabolites (Hollstein 1974; Shih et al. 2003; Reusser 1969; Rao et al. 1963; Sugita et al. 1982; Bowman et al. 1988; Larsen et al. 1988).

**Induction and Identification of Antibacterial Metabolites Produced by *T. harzianum* WC13** One particularly interesting binary competition assay revealed a chemical interaction between *Streptomyces* sp. 4231 and *T. harzianum* WC13, where a small molecule produced and excreted by the bacteria changed the growth morphology and upregulated the production of pigments in the fungus (Fig. 2). Bioassay-guided isolation identified bafilomycin C1 (4), a well-known antifungal agent, as the bacterial-derived small molecule responsible for

inducing pigment formation, but two structural analogs, bafilomycin B1 and D, exhibited no appreciable ability to elicit this response (Figs S31–S32).

Identification of the upregulated fungal metabolites required largescale cultivation of *T. harzianum* WC13 on solid media that was conditioned with either sterilized spent liquid media from a 14-day culture of *Streptomyces* sp. 4231 or with purified bafilomycin C1 (30  $\mu$ M). In both cases, the growth of *T. harzianum* WC13 was significantly stunted, with almost no visible mycelia formation or sporulation, though robust pigmentation of the agar was observed after just four days. Extraction of the solid agar plates and subsequent rounds of RP HPLC purification yielded the isolation of three natural products, cryptenol (1), t22-azaphilone (2), and homodimericin A (3). Both t22-azaphilone (2) and homodimericin A (3) have been previously reported (Vinale et al. 2006, 2009; Mevers et al. 2016). The production of both 2 and 3 are strongly upregulated, approximately 123- and 38-fold, respectively, when grown in the presence of 30  $\mu$ M of bafilomycin C1, while the production of 1 remains relatively unchanged (1.2-fold increase) (Fig. S17). Subsequently, all three metabolites were found to be constitutively expressed in *T. harzianum* T22 (ATCC 20847), a strain that is commonly used as a biocontrol agent (Vinale et al. 2006).

Cryptenol (1) was isolated as a pale-yellow oil having a molecular formula  $C_{13}H_{18}O_2$  based on ESI-QTOF data and requiring five degrees of unsaturation (Fig. S7). The  $^1H$  and  $^{13}C$  NMR data suggested the presence of five olefins and are responsible for all degrees of unsaturation with 10 carbon resonances between 117 and 138 ppm ( $\delta_C$  137.1, 136.1, 133.3, 132.1, 132.0, 131.4, 130.0, 129.6, 128.0, and 117.1), and 11 proton resonances between 5.0 and 6.4 ppm (Fig. S2). Planar structure elucidation was greatly facilitated by the fact that cryptenol contains only one spin-system that could easily be pieced together using gH2BC correlations. Further analysis of the complete 2D NMR dataset [gHSQC, gCOSY, gc2HMBC, and gH2BC (Table 2 and Fig. S1–S6)] led to the identification of the planar structure of cryptenol as trideca-2,4,8,10,12-pentaene-6,7-diol (Fig. 1).

The configuration of the four internal olefins of 1 were determined by  $^3J$  coupling constant analysis, while the relative configuration of the diol was determined using semi-synthetic methods. Measured coupling constants of 15.3 (H-2 and H-3), 15.3 (H-4 and H-5), 15.0 (H-8 and H-9), and 14.9 Hz (H-10 and H-11) are all indicative of *E* configurations for the four internal olefins. The relative configuration of the diol at C-6 and C-7 was determined by preparing the acetonide analog and comparing proton chemical shifts of H-6/H-7, as well as the introduced dimethyl moiety in the acetonide, to two synthetic standards. The acetonide analog of cryptenol was prepared by first reducing all of the olefins with 10% Pd/C and  $H_2$  (g), and then reacting with 2,2-dimethoxypropane.  $^1H$  NMR

**Fig. 2** Induction of pigment formation in *T. harzianum* WC13 when co-cultured with *Streptomyces* sp. 4231

analysis of the derivatived natural product led to the relative assignment of erythro (Fig. S8).

Cryptenol (**1**), homodimericin A (**3**), and t22-azaphilone (**2**) were each evaluated for antimicrobial activity against a range of ecologically relevant microbes, including eight strains of termite-associated actinobacteria, and six soil fungi (*T. harzianum*, *A. nomius*, *Penicillium* sp., *M. anisopliae*, *Trichoderma viride*, and *B. bassiana*). T22-azaphilone exhibited moderate antibacterial activity against every actinobacteria strain tested, including *Streptomyces* sp. 4231, the bafilomycin producer with MICs ranging from 5 to 25  $\mu\text{g}/\text{mL}$  (Fig. S34). No toxicity against any of the fungal pathogens was observed. Cryptenol and homodimericin A were found to be inactive against all microbes screened up to a maximum of 30  $\mu\text{g}$  per spot in a spot-on-lawn assay (Fig. S33).

## Discussion

The carton material in a subterranean termite nest defines a specialized niche, as the fecal material provides nutrients for the growth of a diverse profile of microbes, including chemically-rich actinobacteria that provide chemical defenses against other microbes. Our earlier study showed that a termite colony greatly benefits from the presence of a wide variety of actinobacterial strains present in the carton in preventing infections from pathogenic soil fungi. In fact, inclusion of just one strain of biologically active actinobacteria to the carton material significantly reduces *M. anisopliae* infection rates to termite colonies (Chouvenc et al. 2013b). However, the microbes within the carton material are also in a constant competition with one another for limited nutrients and this continuing competition would be expected to drive a chemical interaction between the competing microbes. The molecules

underlying this chemical interaction would have a range of functions from chemical defense to signaling to acquisition of nutrients. The strong selection pressure on termite-associated actinobacteria to develop an effective and diverse suite of biologically active small molecules is supported by previous studies (Carr et al. 2012; Kang et al. 2016).

Most of the research into insect-associated microbes has been focused on the toxic metabolites produced by the symbiotic bacteria, which have inhibitory activity against ecologically relevant pathogenic fungi with little attention being paid to the chemical response of the pathogen. Constant exposure to an antibiotic pressures the pathogen to evolve response mechanisms, such as detoxification of select antimicrobials, counters to the general effects of antimicrobial such as reactive oxygen species (ROS), repression of antibiotic biosynthesis in the producing organism, active efflux of the antibiotic, and/or production of antibiotics to neutralize the chemical defenses (Duffy et al. 2003; Brakhage and Schroeckh 2011). In this study, we propose that *T. harzianum* WC13 is capable of up-regulating the production of its own small molecules in order to counter the effects of the bacterial derived antifungal agent. The release of bafilomycin C1 by *Streptomyces* sp. 4231 induces the production of several natural products – homodimericin A (**3**), t22-azaphilone (**2**), and cryptenol (**1**) by *T. harzianum* WC13. The prodigious upregulation of homodimericin A and t22-azaphilone production suggests that both have an ecological role in defending *T. harzianum* from the effects of bafilomycin C1. The bafilomycins are known potent and specific inhibitors of fungal vacuolar-type  $\text{H}^+$ -ATPases, which when inhibited causes increases in both cellular pH and oxidative stress (Werner et al. 1984; Dröse and Altendorf 1997). We suggest that the production of homodimericin A, which requires a six-electron non-enzymatic oxidation from its starting material (Mevers et al. 2016; Ma

et al. 2017), would relieve the oxidative stress caused by bafilomycin C1, while t22-azaphilone neutralizes the active threat by inhibiting the growth of *Streptomyces* sp. 4231 and thus ceasing the production of bafilomycin C1.

Our study reveals that the interactions among microbes within a subterranean termite nest are far more complex than previously thought. A subterranean termite colony represents an important resource of essential nutrients for a diverse array of microbes, including strains that are both beneficial and detrimental to the termites. While antibiotic-producing actinobacteria protect the colony from harmful pathogenic fungal infections, some fungi can develop mechanisms to overcome the antibiotic's effect, such as how *T. harzianum* WC13 upregulates the production of homodimericin A and t22-azaphilone in order to combat and neutralize the effect of bafilomycin C. This observation may explain how *T. harzianum* WC13 is able to persist in a termite's nest and saprophytically take over the nest resource once the termite colony and associated actinobacteria community have collapsed (Chouvenc et al. 2013a). This study demonstrates that interactions among microbes in a termite nest is not bipartite, but a complex multipartite system where all organisms compete for resources in antagonistic and beneficial ways.
