In Utero and Early-Life Conditions and Adult Health and Disease

TO THE EDITOR: In their article on the developmental origin of disease, Gluckman et al. (July 3 issue) state that “an altered long-term risk of disease is initially induced through adaptive responses that the fetus or infant makes to cues from the mother about her health or physical state.” This rather narrow definition and the overall focus of the review leave out adverse responses due to maternal exposures to environmental chemicals, occupational hazards, drugs, tobacco smoking, or infection. These factors are likely to make a very large contribution to adult diseases of developmental origin, and they have the advantage of being potentially preventable. Risk assessment of environmental hazards must therefore include the effects of developmental exposures to stimulate better protection of the most vulnerable life stages.

TO THE EDITOR: The article by Gluckman et al. highlights an ongoing fundamental change in medical thinking known as the life-course approach to the development of disease. The “developmental model” of chronic diseases postulates that early-life events affect individual differences in vulnerability to lifestyle and environment. This concept is supported by studies of in utero or at-birth conditions on future diseases by the fact that differences in adult lifestyles only partially explain the development of diseases.

Considering the aging of the worldwide population and the associated increase in the prevalence of chronic diseases, research on the initiating events of such diseases is valuable and necessary, but research on possible synergism or antagonism between in utero and childhood or adulthood conditions on elderly health could be as important for future public health policies. For example, the interaction between education — which has been found to be inversely associated with both multiple chronic conditions and Alzheimer’s disease in the elderly population — and in utero environment might be a pioneering project in this growing research field.

of which need further investigation. Considering the immature stage of the exploration of these effects, we may well currently be looking at the tip of the iceberg, anticipating potential links with adult pulmonary and neurologic diseases like chronic obstructive pulmonary disease and dementia.

To the Editor:
A Case of Conjugal Azathioprine-Induced Contact Hypersensitivity

TO THE EDITOR: A man in his early 30s presented with an intermittent eczematous eruption over the shaft of his penis and scrotum (Fig. 1A). His wife was initially concerned about his fidelity, but a careful history-taking revealed that the rash coincided with his wife's intermittent courses of azathioprine for Crohn's disease. During four courses of such treatment over a 4-year period, her vaginal secretions were yellow, which raised the possibility of secretion of azathioprine or its metabolites that could have led to allergic contact dermatitis in the husband.

Further investigation was undertaken. Both the man and his wife had normal thiopurine methyltransferase levels. Epicutaneous patch testing of petrolatum alone or 1 to 10% of the drug in petrolatum was performed as previously described.1 Azathioprine (pure and tablet forms), its major breakdown product 6-mercaptopurine, and all available tablet excipients were tested on both partners. The husband, but not the wife, reacted to the tablet and pure forms of azathioprine only (Fig. 1B).

THE AUTHORs REPLY: We are pleased with the interest in our review, particularly, as noted, concerning the relevance of developmental exposures (environmental toxins, smoking, and alcohol consumption), intermediary phenotypes (chronic low-grade inflammation), and health outcomes (aging and cognitive decline). Although we focused on metabolic, cardiovascular, and bone disease, the areas most developed, we have little doubt that developmental plasticity and epigenetic change have much greater involvement in the etiology of human disease than has previously been considered. We would urge further research to clarify the involved epigenetic mechanisms, to develop risk-prediction tools that might be applied throughout the life course, and to delineate preventive and interventional strategies.
