Abstract. The study of 2D shapes and their similarities is a central problem in the field of vision. It arises in particular from the task of classifying and recognizing objects from their observed silhouette. Defining natural distances between 2D shapes creates a metric space of shapes, whose mathematical structure is inherently relevant to the classification task. One intriguing metric space comes from using conformal mappings of 2D shapes into each other, via the theory of Teichmüller spaces. In this space every simple closed curve in the plane (a “shape”) is represented by a ‘fingerprint’ which is a diffeomorphism of the unit circle to itself (a differentiable and invertible, periodic function). More precisely, every shape defines to a unique equivalence class of such diffeomorphisms up to right multiplication by a Möbius map. The fingerprint does not change if the shape is varied by translations and scaling and any such equivalence class comes from some shape. This coset space, equipped with the infinitesimal Weil-Petersson (WP) Riemannian norm is a metric space. In this space, the shortest path between each two shapes is unique, and is given by a geodesic connecting them. Their distance from each other is given by integrating the WP-norm along that geodesic. In this paper we concentrate on solving the “welding” problem of “sewing” together conformally the interior and exterior of the unit circle, glued on the unit circle by a given diffeomorphism, to obtain the unique 2D shape associated with this diffeomorphism. This will allow us to go back and forth between 2D shapes and their representing diffeomorphisms in this “space of shapes”. We then present an efficient method for computing the unique shortest path, the geodesic of shape morphing between each two end-point shapes. The group of diffeomorphisms of $S^1$ acts as a group of isometries on the space of shapes and we show how this can be used to define shape transformations, like for instance ‘adding a protruding limb’ to any shape.

Keywords: group of diffeomorphisms, group of shape transformations, shape representation, metrics between shapes, conformal, Riemann mapping theorem, Weil-Petersson metric, geodesic, fingerprints of shapes

1. Introduction

Many different representations for the collection of all 2D shapes, and many different measures of similarity between them have been studied recently (Hildreth, 1984; Kass et al., 1988; Ullman, 1989; Amit 1991; Yuille, 1991; Sclaroff and Pentland, 1995; Kimia et al., 1995; Geiger et al., 1995; Gdalyahu and Weinshall, 1999; Basri et al., 1998; Belongie et al., 2002; Sebastian et al., 2001; Carlsson, 1999). Although significant progress has been made, none are fully satisfactory from the point of view of leading to a successful classification of the collection of all shapes. In part, this shortcoming is due to the fact that human perception may give different meanings to similarity between shapes in different contexts and for different tasks (Biederman, 1985; Mumford, 1991) (see Fig. 1). In this paper, we propose the study of a new approach to measuring the similarity of shapes by applying the mathematical theory of complex analysis. This grows out of a new way of representing shapes.
Representing shapes in a simple way for classification is difficult because of two things: on the one hand, the set of all shapes is inherently infinite dimensional and, on the other hand, it has no natural linear structure. More precisely, the first assertion means that if we map every shape to a point of $\mathbb{R}^n$ by assigning to it $n$ features, there will always be many distinct shapes on which all these features coincide. You cannot capture all the variability of a shape in a finite set of features. The second assertion means that there is no vector space structure on the set of all shapes, no way of adding, subtracting and multiplying by scalars in such a way that the resulting space is a bijection between the two quotient sets: $(\mathbb{R}^n, +, \cdot) \rightarrow \mathbb{R}^n$. If $S$ is the set of 2D shapes and $H$ is the group of maps $(x, y) \mapsto (ax + b, ay + c)$, then the result of this construction is a bijection between the two quotient sets:

$$\text{Diff}(S^1)/\text{PSL}_2(\mathbb{R}) \cong S/H.$$  

Moreover, this quotient space turns out to be equipped with a very remarkable metric, the Weil-Petersson (WP) Riemannian metric. The resulting metric space has two major properties. First, the space has non-positive sectional curvature, and hence there exists a unique geodesic between each two shapes. Defining the integral of the WP-norm along a path as the length of this path, a geodesic is defined as the shortest path connecting the two shapes and its length is the global metric on the space of shapes. The shapes along that path represent a natural morphing of one into the other. Secondly, the resulting space is homogeneous with respect to the group of diffeomorphisms operating on the cosets from the left. Thus, for example, we can transform all shapes into new norms. One can play with these alternatives and work out which shapes in Fig. 1 are closer to the central shape in which metric.

In our method of representing shapes, every shape will define a sort of ‘fingerprint’, which is a diffeomorphism of the unit circle to itself. Such a diffeomorphism is given by a smooth increasing function $f : \mathbb{R} \rightarrow \mathbb{R}$ which is differentiable and satisfies $f(x + 2\pi) = f(x) + 2\pi$ and two functions $f_1, f_2$ define the same diffeomorphism if $f_1(x) \equiv f_2(x) + 2\pi n$. The group of such diffeomorphisms will be denoted by $\text{Diff}(S^1)$. The construction is based on the existence of a conformal mapping from the interior of any shape $\Gamma$ to the interior of the unit disk via the Riemann mapping theorem. Like all conformal maps, it preserves the angles between any two intersecting curves and, moreover, it is unique up to composition with a Möbius-transformation ambiguity.

More precisely, we will show that every simple closed curve in the plane defines an equivalence class of diffeomorphisms $f$. These equivalence classes are the right cosets of these diffeomorphisms modulo the three dimensional subgroup of Möbius maps $\text{PSL}_2(\mathbb{R})$, namely the maps from the complex unit circle $\{z \ | |z| = 1\}$ to itself given by $z \mapsto (az + b)/(\bar{b}z + \bar{a})$. This set of equivalence classes is then written as the quotient $\text{Diff}(S^1)/\text{PSL}_2(\mathbb{R})$. In this assignment, two shapes $\Gamma_1, \Gamma_2$ define the same diffeomorphism only when one shape is gotten from the other by a translation and scaling, i.e. $\Gamma_2 = a \cdot \Gamma_1 + (b, c)$. If $S$ is the set of 2D shapes and $H$ is the group of maps $(x, y) \mapsto (ax + b, ay + c)$, then the result of this construction is a bijection between the two quotient sets:

$$\text{Diff}(S^1)/\text{PSL}_2(\mathbb{R}) \cong S/H.$$
shapes by composing the coset representing them by a
diffeomorphism on the left and this transformation will
preserve the WP distance, take geodesics to geodesics
and hence change the above morphing between any
two shapes into the morphing between the transformed
shapes.

It is essential in this framework to be able to move
back and forth computationally between 2D shapes and
the diffeomorphisms representing them. Moving from
a given shape into the diffeomorphism representing it
can be done by computational implementations of the
Riemann mapping theorem. Several approaches to this
exist in the literature, see 3.1. Perhaps the most effec-
tive way is by using a numerical implementation of the
Schwarz-Christoffel formula, applied to a polygon that
tightly approximates the shape (Driscoll, 1996). But

2. Shapes as Diffeomorphisms of the Circle

In this paper, by a “shape” we mean a simple closed
smooth curve \( \Gamma \) in the plane. Smooth means having
derivatives of all orders (i.e. being \( C^\infty \)), and simple
means that the curves do not intersect themselves. Ev-
erything is based on the Riemann mapping theorem
which states that it is possible to map the unit disc
conformally to the interior of any such shape. The
conformal transformation is unique up to any preced-
ing Möbius transformations mapping the unit disc to
itself (that is, maps of the form \( z \mapsto (az+b)/(\bar{b}z+\bar{a}) \)).
Conformal means that the infinitesimal angle between
each two crossing curves is equal to the infinitesimal
angle between the transformed curves. The nature of
these mappings is shown in Fig. 2, where the im-
age of the radial grid on the unit disc (made out of
concentric circles and lines through the origin) under
this map is shown. Note that the image curves remain
perpendicular.

![Figure 2](image_url)

Figure 2. On the top, the conformal parametrization of the interior
and exterior of an ellipse given by the Riemann mapping theorem,
shown by plotting the images under \( \Phi_- \) and \( \Phi_+ \) of circles around
the origin and radial lines. On the bottom, the “fingerprint” \( \Psi \). The
circled points on the 2 figures are corresponding points. Note the
large derivative of the fingerprint at the points \( \theta = 0, \pi \) cor-
responding to the ends of the major axis and the small derivative at the points
\( \theta = \pi/2, 3\pi/2 \) corresponding to the ends of the minor axis.

2.1. Shapes to Diffeomorphisms

In this whole paper, we associate \( \mathbb{R}^2 \) with the complex
plane \( \mathbb{C} \) and hence we denote planar points by complex
numbers \( u + iv \). We often want to add in the ‘point at
infinity’; adding this in, we get the extended complex
plane, also called the Riemann sphere and denoted by
\( \mathbb{C} \cup \{ \infty \} \).

Further, we denote the unit disc \( \{ z \mid |z| \leq 1 \} \) by
\( \Delta_- \) and the infinite region outside or on the unit disc
\( \{ z \mid |z| \geq 1 \} \) (including \( \infty \)) by \( \Delta_+ \). Observe that using
the transformation \( z \mapsto 1/z \) we can identify \( \Delta_+ \) with
\( \Delta_- \). For every simple closed curve \( \Gamma \) in \( \mathbb{C} \) we denote
by \( \Gamma_- \) its union with the region enclosed by it, and
such that the two parts of the \( w \)-sphere divided by \( \Gamma_{\pm} \) (right), correspondingly, such that \( f_{\pm}(z) = f_{\pm}(\Phi(z)) \) on \( |z| = 1 \).

denote by \( \Gamma_{\pm} \) its union with the infinite region outside \( \Gamma \) (including \( \infty \)). We can think of \( \Gamma_{-} \) and \( \Gamma_{+} \) as a partition of the Riemann sphere into two parts along \( \Gamma \) (see Fig. 3).

Then by the Riemann mapping theorem, for all \( \Gamma \) there exists a conformal map

\[
\Phi_{\pm} : \Delta_{\pm} \to \Gamma_{\pm},
\]

unique up to replacing \( \Phi_{\pm} \) by \( \Phi_{\pm} \circ A \) for any Möbius transformations \( A : \Delta_{\pm} \to \Delta_{\pm} \), \( A = (az + b)/(\bar{b}z + \bar{a}) \). That is, for every two conformal maps \( \Phi_{\pm}^{(1)} \), \( \Phi_{\pm}^{(2)} : \Delta_{\pm} \to \Gamma_{\pm} \), we have that \( \Phi_{\pm}^{(2)} \circ \Phi_{\pm}^{(1)} = A \), where \( A \) is a Möbius map.

This works for \( \Delta^{\pm} \) and \( \Gamma^{\pm} \) too as the point at infinity is no different from other finite points. Spelling this out, under \( 1/z, \Gamma \) is transformed into the inverted simple closed curve \( \Gamma' \) so that \( \Gamma_{\pm} \) is identified with the interior \( \Gamma'_{\pm} \) of \( \Gamma' \). Thus we can apply the Riemann mapping theorem to get a \( \Phi' \) from \( \Delta_{\pm} \) and \( \Gamma'_{\pm} \). Composing this conformal map with inverse on both sides, i.e. \( \Phi_{\pm}(z) = 1/\Phi'(1/z) \), we get a conformal map of the exteriors

\[
\Phi_{\pm} : \Delta_{\pm} \to \Gamma_{\pm}.
\]

\( \Phi_{\pm} \) is also unique up to Möbius transformations as above. But now we can do better with \( \Phi_{\pm} \): we take the unique Möbius map \( A \) so that, replacing \( \Phi_{\pm} \) by \( \Phi_{\pm} \circ A \), we achieve the extra normalization that \( \Phi_{\pm} \) carries \( \infty \) to \( \infty \), and that its differential carries the real positive axis of the \( \Delta \)-plane at \( \infty \) to the real positive axis of the \( \Gamma \)-plane at \( \infty \). Thus, we eliminate the Möbius ambiguity of \( \Phi_{\pm} \) for every \( \Gamma \), and make \( \Phi_{\pm} \) unique. An example of this construction is shown at the top in Fig. 2, where the curve \( \Gamma \) is an ellipse.

The goal of this construction is to define the map

\[
\Psi \doteq \Phi_{\pm}^{-1} \circ \Phi_{\pm},
\]

which it is defined on the unit circle \( S^1 \). (Note that \( \Phi^{\pm}(S^1) = \Gamma \), and \( \Phi_{\pm}^{-1}(\Gamma) = S^1 \).) \( \Psi : S^1 \to S^1 \) is a diffeomorphism, which can be thought of as a periodic, real-valued function from \([0, 2\pi] \) to \([0, 2\pi]\), having a positive derivative everywhere. \( \Psi \) is a uniquely-identifying fingerprint of the shape \( \Gamma \). The fingerprint of the ellipse is also shown in Fig. 2.

From the Möbius-transformation ambiguity left in \( \Phi_{\pm} \), we can see that by the construction of \( \Psi \) every simple closed curve \( \Gamma \) induces a diffeomorphism \( \Psi : S^1 \to S^1 \), which is unique up to composing on the right by a diffeomorphism \( A : S^1 \to S^1 \) coming from the restriction to \( S^1 \) of any Möbius transformation \( A : \Delta_{\pm} \to \Delta_{\pm} \).

If, as in the introduction, we denote the coset space\(^{5}\) by \( \text{Diff}(S^1)/\text{PSL}_2(\mathbb{R}) \) and we denote the space of simple closed smooth curves \( \Gamma \) by \( \mathcal{S} \), then our construction of \( \Psi \) gives us the ‘fingerprint’ map:

\[
\mathcal{S} \to \text{Diff}(S^1)/\text{PSL}_2(\mathbb{R}).
\]

2.2. Diffeomorphisms to Shapes: Welding

Remarkably, this map is nearly a bijection. In fact, every coset \( \Psi \cdot \text{PSL}_2(\mathbb{R}) \) comes from some shape \( \Gamma \) and two shapes \( \Gamma_1, \Gamma_2 \) give the same coset if and only if they differ by a translation and scaling. If \( \mathcal{S} \) is the quotient of shapes modulo translations and scalings, the final result is

\[
\mathcal{S} \cong \text{Diff}(S^1)/\text{PSL}_2(\mathbb{R}).
\]

To obtain \( \Gamma \), \( \Phi_{-} \) and \( \Phi_{+} \) corresponding to any coset, we first pick any \( \Psi \) in the coset. The ‘high level’ way of finding \( \Gamma \) is to construct an abstract Riemann surface \( X \) by ‘welding’ \( \Delta_{\pm} \) and \( \Delta_{-} \) using the map \( \Psi \) to glue their boundaries together and apply the result that any Riemann surface which is topologically a 2-sphere – like \( X \) – is, in fact, conformally isomorphic to \( \hat{\mathbb{C}} \) via some map \( \Phi \). Then \( \Phi_{\pm} \) are just the restrictions of \( \Phi \) to \( \Delta_{\pm} \) and the shape \( \Gamma \) is nothing but the image of the unit circle in the welded surface \( X \) under \( \Phi \). This construction is illustrated in Fig. 3.

A less abstract way to prove weldings exist is to use a celebrated existence theorem of B. Bojarski and...
L. Bers [9, p. 10]. We sketch the proof without details. We use the standard abbreviations:

\[ f_1 = \frac{1}{2}(f_2 - if_3), \quad f_2 = \frac{1}{2}(f_1 + if_3). \]

The theorem states that for any \( c < 1 \) and any complex valued function \( \mu(z) \) with \( |\mu(z)| \leq c \) (called a Beltrami differential), the partial differential equation:

\[ \frac{\partial}{\partial x}(f\mu) + \frac{\partial}{\partial y}(f\mu) = 0 \]

has a complex valued solution\(^6\). We get the \( \mu \) from \( \Psi \) as follows. First define \( G : \Delta_+ \to \Delta_- \) by:

\[ G(e^{i\theta}) = e^{i\Psi(\theta)}. \]

Then let \( \mu = G_z/G_\bar{z} \) on \( \Delta_- \) (one can readily check that this works out to be \( e^{i(\frac{\bar{z}}{z})} \) and \( \mu = 0 \) on \( \Delta_+ \). With this \( \mu \), solve the above equation for the function \( F \). Because \( \mu = 0 \) on \( \Delta_+ \), \( F \) must be a conformal map on \( \Delta_+ \), hence it extends to \( \infty \) and we can normalize it to have positive real derivative there. Let \( \Phi_+ \) be \( F \) on \( \Delta_+ \). Note that \( G \) satisfies the equation on \( \Delta_- \) and, by standard arguments, any other solution there is \( G \) followed by an analytic function (that is a map with complex derivatives but which is not everywhere conformal because they can be zero). So let \( \Phi_- \) be the analytic function \( G \circ \Gamma^{-1} \) on \( \Delta_- \). Then \( \Phi_- \circ G \equiv \Phi_+ \) on the unit circle, as required.

2.3. Shapes with Base Points

We have now seen that shapes, up to scaling and translation, are represented by cosets \( \Psi \cdot \text{PSL}_2(\mathbb{R}) \subset \text{Diff}(S^1) \). An important variant of this representation concerns shapes with base points, that is pairs \( \{\Gamma, P\} \) where \( P \) is a point in the interior of \( \Gamma \). The result is that shapes with base points are represented by cosets \( \Psi \cdot \text{ROT}(S^1) \subset \text{Diff}(S^1) \) where \( \text{ROT}(S^1) \) is the group of rotations \( \theta \mapsto \theta + \phi \) of the circle. Note that \( \text{ROT}(S^1) \subset \text{PSL}_2(\mathbb{R}) \) as the rotation through angle \( \phi \) is given by the map \( z \mapsto (az + b)/(\bar{b}z + a) \) for \( a = e^{i/2}, b = 0 \).

This representation is a simple extension of what we have already seen: having a base point \( P \) in the interior of the shape \( \Gamma \) allows one to normalize the conformal map \( \Phi_- \) so that \( \Phi_-(0) = P \). This fixes \( \Phi_- \) up to right multiplication by a rotation, hence \( \Psi \) is also determined up to such a right multiplication. This state of affairs is often depicted by a ‘commutative diagram’:

\[
\text{Diff}(S^1)/\text{ROT}(S^1) \cong \{\Gamma, P\}/H \\
\text{Diff}(S^1)/\text{PSL}_2(\mathbb{R}) \cong \{\Gamma\}/H
\]

where the vertical arrows denote the maps given by (i) passing from the small cosets mod \( \text{ROT} \) to the larger cosets mod \( \text{PSL}_2 \); and (ii) passing from a shape with base point to a shape without base point.

Closely related to this is the following remark: if a coset \( \Psi \cdot \text{PSL}_2(\mathbb{R}) \) represents the shape \( \Gamma \), then the cosets \( A \circ \Psi \cdot \text{PSL}_2(\mathbb{R}) \), for various \( \text{M"obius maps} \ A \in \text{PSL}_2(\mathbb{R}) \) represent the shapes \( B(\Gamma) \) for those \text{complex M"obius} maps \( B \in \text{PSL}_2(\mathbb{C}) \) such that \( B^{-1}(\infty) \) lies outside \( \Gamma \). Recall that complex \( \text{M"obius maps} \) are the maps of the extended complex plane given by \( z \mapsto (az + b)/(cz + d) \). To see this, use the definition \( \Psi = \Phi_+^{-1} \circ \Phi_- \). Then multiplying \( \Psi \) on the right by \( A \) is the same as replacing \( \Phi_+ \) by \( \Phi_+ \circ A \). Now \( \Phi_+ \circ A \) is a good conformal map of the exterior of the unit circle onto the exterior of \( \Gamma \), only it doesn’t have the right normalization any more as it doesn’t carry \( \infty \) to \( \infty \). In fact, \( Q = \Phi_+(\infty) \) is some point in the exterior of \( \Gamma \). Choose a complex \( \text{M"obius} \) map \( B \) so that \( B^{-1}(\infty) = Q \). Further require that \( B^{-1} \) carry the positive real axis tangent direction at \( \infty \) to the tangent direction at \( Q \) which is the image of the positive real direction under \( \Phi_+ \circ A \). Then \( B \circ \Phi_+ \circ A \) is fully normalized, carrying \( \infty \) to itself and carrying the positive real direction at \( \infty \) to itself. Thus \( \Phi_+ = B \circ \Phi_+ \circ A \) and \( \Phi_+ = B \circ \Phi_+ \). Thus the fingerprint of \( B(\Gamma) \) is \( \Psi' = (\Phi_+^{-1}) \circ \Phi_- = A \circ \Phi_+^{-1} \circ \Phi_- = A \circ \Psi \).

2.4. The Homogeneous Structure of \( \tilde{S} \)

Any group \( G \) operates, of course, on any coset space \( G/H \) by left multiplication, hence, as a result of the above construction, \( \text{Diff}(S^1) \) operates on the space of shapes \( \tilde{S} \). A concrete way of defining this action is this: to transform any \( \Gamma \in \tilde{S} \) by a group element \( \Psi \), we construct the conformal map \( \Phi_+ : \Delta_+ \to \Gamma_+ \) hence we get the map \( \Psi' = \Phi_+ \circ \Psi \circ \Phi_+^{-1} \) from \( \Gamma_+ \) to itself. Then we use the same welding trick by cutting open \( \tilde{C} \) along \( \Gamma \) and rewelding it with the map \( \Psi' \). The result can be conformally mapped to the extended sphere, taking \( \Gamma \) to a new curve \( \Gamma' \). This way we get a \textit{transitive} group operation on \( \tilde{S} \).
3. Computing Shapes from Diffeomorphisms and Vice Versa

3.1. Schwarz-Christoffel: From Shapes to Diffeomorphisms

There seem to be three published methods of computing the conformal mapping from the unit disk to the interior of a simple closed curve $\Gamma$:

The Schwarz-Christoffel method is like this: start by approximating $\Gamma$ by a polygon. Let $z$ be the complex coordinate in the unit disk, and let $\{a_i\}$ be the points on the unit circle which will map to the vertices of the polygon and let $\{\pi \alpha_i\}$ be the angles of the polygon at these vertices. Then for some $C_1, C_2$:

$$\Phi(z) = C_1 \int_0^z \prod_i (z - a_i)^{\pi \alpha_i} \, dz + C_2.$$  

For instance, if the polygon is a square, then the conformal map of the unit disk to its interior is given by the elliptic integral:

$$\Phi(z) = C_1 \int_0^z \frac{dz}{\sqrt{1 - z^2}} + C_2.$$  

This method has been implemented in the excellent package ‘sc’ by Tobin Driscoll (cited above), based on joint work with L.N. Trefethen (1996). The key problem is that one is usually given only the points $\Phi(a_i)$ and must compute $\{a_i\}$ at the same time as $\Phi$. Moreover, they are non-unique as, for any Möbius map $A$, $\Phi' = \Phi \circ A$, $a_i' = A^{-1}(a_i)$ are equally good solutions. The program allows you to specify the point $\Phi(0) \in \text{Int}(\Gamma)$ to get the best looking and best behaved solution. We use this package for our examples in Section 4 below.

3.2. From Diffeomorphisms to Shapes: The First Method of Welding

3.2.1. Reducing Welding to Coupled Elliptic Boundary Value Problems. Setting the equations for the conformal map $f$ (see Fig. 3). We consider $\Delta_-$ and $\Delta_+$ as a partition of the Riemann sphere into two parts along the unit circle $\Delta$, and $\Gamma_-$ and $\Gamma_+$ as a partition of the Riemann sphere into two parts along $\Gamma$, as explained in Sec. 2.1 (see Fig. 3). We associate the complex-plane variable $z$ with the $\Delta$-sphere, and the complex-plane variable $w$ with the $\Gamma$-sphere. We will assume that $0 \in \Gamma_-$ in order to normalize the map $\Phi_-$ as well as $\Phi_+$ by asking that $\Phi_-(0) = 0$. Given a diffeomorphism $\varphi : \Delta \to \Delta$, we seek a function $f(z)$ from the $z$-sphere minus the unit circle to the $w$-sphere, complex analytic on $|z| < 1$ with boundary values $f_{|z|=1} = f_-$, and complex analytic on $|z| > 1$ with $f_{|z|=1} = f_+$, such that

$$f(0) = 0, \quad f(\infty) = \infty, \quad f_{-}(z) = f_{+}(\varphi(z)), \quad |z| = 1$$  

(2)

Defining $g$, a function of $f$ which is more convenient to compute. Note that $f(z)/z$ has finite non-zero limiting values at 0 and $\infty$, hence it has a single-valued logarithm in $\Delta_-$ and $\Delta_+$. Thus we may define $g(u)$ by

$$\log \left( \frac{f(e^{iu})}{e^{iu}} \right) = g(u), \quad u \in \mathbb{C} - i\mathbb{R}$$  

(3)

so that $g(u + 2\pi i) \equiv g(u)$.

Now,

$$\text{Re}(u) \to -\infty \Rightarrow |e^{iu}| \to 0 \Rightarrow f(e^{iu}) \approx c_1 e^{iu} \Rightarrow g(u) \approx \log c_1,$$  

(4)

and

$$\text{Re}(u) \to \infty \Rightarrow |e^{iu}| \to \infty \Rightarrow f(e^{iu}) \approx c_2 e^{iu} \Rightarrow g(u) \approx \log c_2,$$  

(5)

for some constants $c_1$ and $c_2$. Without loss of generality, we can replace $f$ by $c_2^{-1} f$ so that $c_2 = 1$, and $g(u) \approx 0$ as $\text{Re}(u) \to +\infty$.

We define $\Psi : \mathbb{R} \to \mathbb{R}$, satisfying $\Psi(\theta + 2\pi) = \Psi(\theta) + 2\pi$ by $\varphi(e^{i\theta}) = e^{i\Psi(\theta)}$. Then,

$$g_-(i\theta) = \log(f_-(e^{i\theta})) - i\theta = \log(f_+(\varphi(e^{i\theta}))) - i\theta = \log(f_+(e^{i\Psi(\theta)})) - i\theta = g_+(i\Psi(\theta)) + i\Psi(\theta) - i\theta.$$  

(6)
Thus we get a new welding condition on the imaginary axis
\[ g_-(i\theta) = g_+(i\Psi(\theta)) + i(\Psi(\theta) - \theta). \] (7)
Note that if Eq. 7 holds at \( \theta \) then it also holds at \( \theta + 2\pi \).

**Setting the equations for** \( g \)'s imaginary part \( k \). (\( h \) is then known from \( k \)) Now let
\[ g(u) = h(u) + ik(u), \] (8)
where \( h, k \) are real. Then,
- \( h, k \) harmonic if \( \text{Re}(u) < 0, \text{Re}(u) > 0 \)
- \( h, k \rightarrow 0 \) if \( \text{Re}(u) \rightarrow +\infty \)
- \( h, k \) periodic if \( \text{Re}(u) \rightarrow -\infty \) (9)
- \( h, k \) harmonic if \( u \rightarrow u + 2\pi i \).

Furthermore, from Eq. 7 we get that
\[ h_-(i\theta) = h_+(i\Psi(\theta)) \]
\[ k_-(i\theta) = k_+(i\Psi(\theta)) + \Psi(\theta) - \theta. \] (10)

By the Cauchy-Riemann equations, if \( u = s + i\theta \), we have for \( s < 0, s > 0 \) that
\[ \frac{\partial h}{\partial \theta} = -\frac{\partial k}{\partial s}, \quad \frac{\partial h}{\partial s} = \frac{\partial k}{\partial \theta}. \] (11)

For \( s = 0 \) this gives
\[ -\frac{\partial k}{\partial s} = \frac{\partial h}{\partial \theta} = \Psi(\theta) \frac{\partial h_+}{\partial \theta} = -\Psi(\theta) \frac{\partial k_+}{\partial s}. \] (12)

Thus, we can conclude the following conditions on \( k \)
- \( k \) harmonic on \( s < 0, s > 0 \)
- \( k \) periodic w.r.t. \( \theta \) \( \rightarrow \theta + 2\pi \)
- \( k \rightarrow 0 \) if \( s \rightarrow \infty, k \rightarrow c \) if \( s \rightarrow -\infty \) (13)
- \( k_+|_{\theta=\theta} = k_+|_{\psi(\theta)} + \Psi(\theta) - \theta \) on \( s = 0 \)
- \( \frac{\partial k}{\partial s}|_{\theta=\theta} = \Psi'(\theta) \frac{\partial k_+}{\partial s}|_{\psi(\theta)} \) on \( s = 0 \),
for some real constant \( c \) which comes implicitly from the equations. Note that Eq. 13 is in fact an equation for a real function \( k \), of the two real variables \( s \) and \( \theta \).

Having solved it for \( k = k(s, \theta) \) we get \( h = h(s, \theta) \) as

![Image](https://example.com/image.png)

**Figure 4.** (\( s, \theta \)) \( k \)-grid on the \((s, \theta)\) plane. In blue over the grid points, a schematic sketch of the three types of equations involved in the numeric solution of \( k \), as described in Sec. 3.2.2: the zero derivatives at the external boundaries \( (s = \pm \delta) \), described by the equal signs (Neuman boundary conditions), the template of the Laplacian mask applied to internal grid points \( (s \neq \pm 0, \pm \delta) \), and the 9 grid points (circled) involved in the internal boundary condition for every internal-boundary grid point \( (s = \pm 0) \). The square inset demonstrates the three staggered grids, for the functions \( k, h \) and \( g \).

Every grid point is represented by the corresponding letter.

The conjugate function of \( k \), via the Cauchy-Riemann relations in Eq. 11.

\[ f \text{ is then known from } k \text{ and } h. \]

From Eq. 9 and Eq. 8 we get that
\[ f(\epsilon + i\hat{\theta}) = e^{h(s+i\theta)+i[k(s+i\theta)+\hat{\theta}]} \] (14)

Since \( \Gamma \) is given by \( f(\theta)|_{s=\pm\hat{\delta}} \), we have that \( h(\theta)|_{s=\pm\hat{\delta}} \) and \( k(\theta)|_{s=\pm0} \) describe the magnitude and angle, respectively, of the complex-plane vectors delineating \( \Gamma \) as a periodic function of \( \theta \).

3.2.2. **Solving the Elliptic Problem Numerically**

Given a diffeomorphism \( \Psi \), we solve Eq. 13 for the \( \theta \)-periodic function \( k = k(s, \theta) \) on the plane branch \( \theta \in \{0, 2\pi\} \) and \( -\infty < s < \infty \). We conveniently set three different, staggered grids on \((s, \theta)\), with uniform meshsize \( \delta > 0 \) for the three functions \( k, h \) and \( g \) (see the square inset in Fig. 4). In practice, we cut off the \( s \) direction into \( -\hat{\delta} \leq s \leq \hat{\delta} \), for some \( \hat{\delta} > 0 \), at which the values of \( k, h \) and \( g \) already converge to constants (cf. Eq. 9). Solving for \( k \) on the \( k \)-grid, we use Eq. 11 to compute \( h \) on the \( h \)-grid, and interpolating both to get \( g \) on the \( g \)-grid. It is the values of \( g \) on \( s = \pm 0 \) that fix the resulting curve \( \Gamma \). In practice, having \( k \), we directly compute \( h \) on \( s = \pm 0 \), at the \( k \)-grid points, as explained at the end of Sec. 3.2.2.

**Solving for** \( k \): setting the \( s \)-grid and three types of numerical equations (see Fig. 4). Solving for \( k(s, \theta) \), we define the \( (s, \theta) \) \( k \)-grid, by indexing with \( i, j \in \mathbb{N} \) an \( s \)-grid: \( s_j \in \{ -\hat{\delta}, (-\hat{\delta} + \delta), (-\hat{\delta} + 2\delta), \ldots, -\delta, -\delta, 0, +0, \delta, 2\delta, \ldots, (\hat{\delta} - \delta), (\hat{\delta} - \delta), \} \), and a \( \theta \)-grid: \( \theta_i \in \{ 0, \delta, 2\delta, \ldots, (2\pi \)
- \delta \} \) (for which the index \( j \) applies periodically). We set three different types of equations.

**Setting the Laplacian-mask equations.** First we have the basic simplest second-order discretization of the Laplace equation holding for every internal point, \( k \) being harmonic, that is: \( \forall j \) and \( \forall s_i \neq \pm \delta, \pm 0 \) we have
\[
0 = \frac{1}{\delta^2} (-4k(s_i, \theta_j) + k(s_{i-1}, \theta_j) + k(s_{i+1}, \theta_j) \\
+ k(s_j, \theta_{j-1}) + k(s_j, \theta_{j+1})).
\]

(15)

**Setting the Neumann-boundary-condition equations.** Second, accounting for \( k \)'s convergence to constants at \( s = \pm \infty \), we set Neuman boundary conditions at the external boundaries \( s_i = \pm \delta \)
\[
k(-\delta, \theta_j) = k(-\delta + \delta, \theta_j) \quad \forall j \\
k(\delta, \theta_j) = k(\delta - \delta, \theta_j) \quad \forall j
\]

(16)

**Setting the internal-boundary-condition (welding) equations.** Third, we have the \( k \)-value, and \( k \)-derivative pair of welding equations from Eq. 13, between the internal boundaries \( s = -0 \), associated with \( k_- \), and \( s = +0 \) associated with \( k_+ \).

For every \( j \) we will associate one such pair of equations with every value \( k(-0, \theta_j) \), and similarly with every value \( k(+0, \theta_j) \). We separate the equations for \( k_- \) from those for \( k_+ \) because the values of \( \Psi(\theta_j) \) involved in the equation for \( k(-0, \theta_j) \) do not necessarily fall on some grid line \( \theta_j \); since \( \Psi \) is a continuous welding diffeomorphism that does not typically send \( \theta_j \) into some other grid line \( \theta_j \). (Symmetrically, when focusing on the pair of welding equations for \( k(+0, \theta_j) \) we may have that \( \Psi^{-1}(\theta_j) \) is not a grid line.)

For every grid line \( \theta_j \) we use the following second-order discretizations for \( \frac{\partial k}{\partial s}_{|_{s=0,\theta}} \)
\[
\frac{\partial k}{\partial s}_{|_{s=-0,\theta}} = \frac{3}{2\delta}k(-0, \theta_j) - \frac{2}{\delta}k(-0 - \delta, \theta_j) \\
+ \frac{1}{2\delta}k(-0 - 2\delta, \theta_j) + O(\delta^2).
\]

(17)

and
\[
\frac{\partial k}{\partial s}_{|_{s=+0,\Psi(\theta_j)}} = -\frac{3}{2\delta}k(+0, \Psi(\theta_j)) + \frac{2}{\delta}k(+0 + \delta, \Psi(\theta_j)) \\
- \frac{1}{2\delta}k(+0 + 2\delta, \Psi(\theta_j)) + O(\delta^2).
\]

(18)

To replace the first term on the right, \( k_s(+0, \Psi(\theta_j)) \), we may simply use the value of \( k \) at the grid point \((0, \theta_j)\), via the \( k \)-value welding equation from Eq. 13
\[
k_{+|_{s=+0,\Psi(\theta_j)}} = k(-0, \theta_j) - \Psi(\theta_j) + \theta_j.
\]

(19)

The other two values of \( k \) participating in Eq. 18 may each be simply interpolated from the nearest three grid points along the \( \theta \)-direction. We use three such values to keep an approximation of order \( \delta^2 \). More precisely, for every \( s \)-column, and specifically for \( s = +0 + \delta \) and \( s = +0 + 2\delta \), we can write the exact interpolation relations
\[
k_{s=\pm \infty} = (\Psi - \theta_{j_1})(\Psi - \theta_{j_1})k_{s=\theta_{j_1}} + O(\delta^2)
\]

(20)

\[
(\Psi - \theta_{j_2})(\Psi - \theta_{j_2})k_{s=\theta_{j_2}} + (\Psi - \theta_{j_2})(\Psi - \theta_{j_3})k_{s=\theta_{j_2}}
\]

\[
(\theta_{j_2} - \theta_{j_1})(\theta_{j_2} - \theta_{j_1})k_{s=\theta_{j_2}} + (\theta_{j_2} - \theta_{j_1})(\theta_{j_2} - \theta_{j_2})k_{s=\theta_{j_2}},
\]

where \( \theta_{j_1}, \theta_{j_2}, \theta_{j_2} \), and \( \theta_{j_2} \), are the closest grid points to \( \Psi \).

Substituting Eq. 19 and Eq. 20 in Eq. 18 we get from the last equation in Eq. 13 an equation between exactly 9 grid values. We associate this equation with the unknown \( k(-0, \theta_j) \). A similar equation is associated with \( k(+0, \theta_j) \) for every \( \theta_j \). Together with Eq. 15 and Eq. 16 we have thus associated one equation with every grid point \((s_i, \theta_j)\). See Fig. 4 for exemplifying the three different types of equations.

**Regularizing the system of equations for \( k \).** Notice however that the solution is still not uniquely fixed. Adding a constant to any solution of this system will keep it a solution still. Thus the system is singular. So we first need to add one more equation that will determine that constant. Recalling that \( k \to 0 \) as \( s \to -\infty \) (cf. Eq. 9), a natural numerical equivalent condition would be that \( \int_{\theta=0}^{\infty} k(\infty, \theta) = 0 \), and in its discretized form
\[
\delta \sum_{j} k(\delta, \theta_j) = 0.
\]

(21)

(We could in principle set a one grid-point value of \( k \) but this is less favorable numerically in general, and somewhat less amenable when carrying the set of differential equations in Eq. 13 to other, coarser grids.)

We now have one equation more than variables. Up to round-off errors the system has a unique solution since the equations are dependent. But for the numerical solver to work properly we add another unknown, say \( \epsilon \), to some of the equations making the new system non-singular. Since the system without this addition has a unique solution \( \epsilon \) will actually turn out to be zero up to round-off errors. We have chosen to add \( \epsilon \) to each
of the $k$-derivative welding equations, although other choices could be made as well.

**Having computed $k$ we compute $h$ and then $g$, on $s = -1$.** Having computed the values of $k$ over the $k$-grid we note that in order to get the resulting shape $\Gamma$ we only need the values of $g(s, \theta)$ and hence of $h(s, \theta)$ at either one of the internal boundaries $s = \pm 0$. We can use a discretized version of the first Cauchy-Riemann equation presented in Eq. 11 in order to approximate $\partial_{\theta}$ where $\frac{\partial}{\partial s}|_{s=\pm 0}$ on $s = \pm 0$, at exactly midpoints between the $k$-grid points. Specifically we write

$$h(-0, \theta_{j+1}) - h(-0, \theta_j) = -\frac{1}{2} \left( \frac{\partial k}{\partial s} |_{s=0, \theta_{j+1}} + \frac{\partial k}{\partial s} |_{s=0, \theta_j} \right) + O(\delta^2),$$

(22)

where $\frac{\partial k}{\partial s} |_{s=0, \theta_{j+1}}$ and $\frac{\partial k}{\partial s} |_{s=0, \theta_j}$ were already computed during the process of computing $k$, via Eq. 17. We can easily integrate the values $\{h(-0, \theta_j)\}_j$ out of their differences computed in Eq. 22, up to a global additive constant that does not matter in terms of the resulting $\Gamma$.

From $\{k(-0, \theta_j)\}_j$ and $\{h(-0, \theta_j)\}_j$ we have $\{g(-0, \theta_j)\}_j$ via Eq. 8, and can get $\{f(-0, \theta_j)\}_j$ via Eq. 3, and eventually $\Gamma$.

**3.3. A Second Method of Welding**

The second algorithm is based on the Hilbert transform. Recall that for functions on the real line, the Hilbert transform is convolution with the singular kernel $1/\pi x$ and that it multiplies the fourier transform of the function by $-i \cdot \text{sign}(\xi)$. In our case, we are dealing with functions on the circle and the modified Hilbert transform is convolution with $\text{ctn}(\theta/2)$ or, equivalently, multiplication of the fourier coefficients by $-i \cdot \text{sign}(n)$. For any function $f \in L^2(S^1)$, let $H(f)$ be its Hilbert transform in this sense.

Now consider the function $f^+$ as above. It is meromorphic on $\{|z| \geq 1\} \cup \infty$ and with a simple pole and positive real derivative at $\infty$, hence it has an expansion:

$$f_+(z) = bz + a_0 + a_1z^{-1} + a_2z^{-2} + \cdots, \quad b > 0.$$ 

Since $\Gamma$ is only defined up to scalings, we can normalize so that $b = 1$. Thus, on the unit circle:

$$f_+(e^{i\theta}) = e^{i\theta} + \sum_{n \in \mathbb{Z}} a_n e^{-i\pi \eta \theta}.$$ 

Let $F(\theta) = f_+(e^{i\theta})$. Then

$$iH(F)(\theta) = 2e^{i\theta} + a_0 - F(\theta).$$

On the other hand, we know that $f_-$ is holomorphic on $\{|z| \leq 1\}$, so it has the expansion:

$$f_-(z) = c_0 + c_1z + c_2z^2 + \cdots.$$ 

Since $f_-(e^{i\theta}) = F(\Psi(\theta))$, we get:

$$iH(F \circ \Psi)(\theta) = (F \circ \Psi)(\theta) - c_0.$$ 

Thus, by subtraction, we get:

$$iH(F \circ \Psi(\theta)) - iH(F) = 2F - (a_0 + c_0) - 2e^{i\theta}. $$

We may replace $F$ by $F - \frac{a_0 + c_0}{2}$ since $\Gamma$ is only defined up to a translation. Letting $K(F) = i/2(iH(F) - H(F \circ \Psi \circ \Psi^{-1}))$, we get the integral equation

$$K(F) + F = e^{i\theta}$$

(23)

for $F$.

We can calculate $K$ as follows. Let $\chi = \Psi^{-1}$ be the inverse of the welding map. Then:

$$K(F)(\theta_1) = i \int_{S^1} \text{ctn} \left( \frac{\theta_1 - \theta_2}{2} \right) F(\theta_2) d\theta_2 - \text{ctn} \left( \frac{\chi(\theta_1) - \theta_1}{2} \right) F(\Psi(\theta_3)) d\theta_3$$

$$= i \int_{S^1} \text{ctn} \left( \frac{\theta_1 - \theta_2}{2} \right) - \chi'(\theta_2) \text{ctn} \left( \frac{\chi(\theta_1) - \chi(\theta_2)}{2} \right) F(\theta_2) d\theta_2$$

and it is easily seen that the poles in the kernel cancel out. Remarkably, $K$ is therefore a smooth integral operator. By the Fredholm alternative, $F$ can be solved for as $(I + K)^{-1}(e^{i\theta})$ provided that $I + K$ has no kernel. Running the above argument backwards, it is easily seen that a function in its kernel would define a holomorphic function on the compact surface gotten by welding and this would have to be a constant. These are not in the kernel as $K$ kills constants. Thus the welding is transformed into solving a well-posed integral equation.

Numerically, we sample $F$ on some grid and need only convert the linear map $K$ into a suitable matrix.
The only difficult point is to not allow the singularity of the Hilbert kernel to cause problems. To address this, we use the fact that the Hilbert kernel can be integrated explicitly:

$$\int_a^b \frac{\sin(x/2)}{\sin(b/2)} dx = 2 \log \left( \left| \frac{\sin(a/2)}{\sin(b/2)} \right| \right).$$

Note that even if $0 \in (a, b)$, the result is correct provided the integral is taken to be its principal value (i.e. the limit of its values on the domain $[a, -\epsilon] \cup [\epsilon, b]$ as $\epsilon \to 0$.

The linear map $K$ is then converted into a matrix as follows: let $F(\theta)$ be given at points $\theta = \theta^s$, e.g. $\theta^s = 2\pi a/N$. Let $\theta^{s+1/2} = (\theta^s + \theta^{s+1})/2$. The divide the interval $[0, 2\pi]$ into intervals $I_{2\pi} = [\theta^{s-1/2}, \theta^{s+1/2}]$. Assume $F$ is approximately constant on each interval $I_{2\pi}$. Then replacing $F(\theta)_{2\pi}$ for $\theta_{2\pi} \in I_{2\pi}$ by $F(\theta^{s+1/2})$, and setting $\theta_1 = \theta^{s+1/2}$, the integral for $K$ over $I_{2\pi}$ gives the matrix entry:

$$K_{a, \beta} = i \cdot \log \left( \frac{\sin(\theta^s - \theta^{s+1/2}) \cdot \sin(\chi(\theta^{s+1/2}) - \chi(\theta^{s-1/2}))}{\sin(\theta^s - \theta^{s+1/2}) \cdot \sin(\chi(\theta^{s+1/2}) - \chi(\theta^{s-1/2}))} \right).$$

4. Examples of Fingerprints and Their Shapes

We implemented solvers both for the welding equations described in Eq. 13, according to Sec. 3.2.2 and for Eq. 23 in Sec. 3.3. To go back and forth between $\mathbb{S}$ and $\text{Diff}(S^1)/\text{PSL}_2(\mathbb{R})$ we start with a shape $\Gamma \subseteq \mathbb{S}$, and using the Schwarz-Christoffel transformation (Sec. 3.1) we compute the two confluent mappings, $\Phi_-$ and $\Phi_+$ of the unit disc to the interior and exterior of the shape, correspondingly as explained in Sec. 2.1. We may then obtain a diffeomorphism $\Psi$ from the coset in $\text{Diff}(S^1)/\text{PSL}_2(\mathbb{R})$ describing $\Gamma$ by defining $\Psi = \Phi_+ \circ \Phi_-^{-1}$. To go back from $\Psi$ to $\Gamma$ we follow Sec. 3.2.2 or Sec. 3.3 for welding in order to get $f$, and demonstrate that the resulting $\Gamma$ is indeed the one we started with.

The first example is a family of shapes for which the conformal mappings $\Phi_-$ and $\Phi_+$ can be solved analytically: these are the lens or eye shaped regions bounded by two circular arcs meeting at two corners. Figure 5 shows how the conformal map to the interior one such shape can be constructed. To get any other eye shaped region, one need only change the power in the third step and change the Möbius map used in the final step. If the angle of the eye at its corners is $\alpha \pi$, then one uses $z_3 = z_2^\alpha$. The same method gives us the conformal to the exterior, except that as the exterior angle is $(2-\alpha)\pi$, one uses $z_3 = z_2^{2-\alpha}$. Applying this construction to both the interior and the exterior, we can verify that the fingerprints which give eye shaped regions are all of the form:

$$\Psi_{\beta}(\theta) = 2 \cdot \arctan \left( \frac{\tan(\theta/2)^\beta}{\tan(\theta/2)} \right),$$

where $\tan^\beta = \text{sign}(\tan(\theta/2)) \tan |\theta|^\beta$. (24)

Here, if $\alpha \pi$ is the angle of the corner of the eye, then $\beta = \alpha/(2 - \alpha)$. The fingerprint for one eye shape is shown in Fig. 6.

It is striking that the formula for the fingerprint of eye-shaped regions is of the form $f^{-1}(\beta \cdot f(\theta))$: in fact define $f_1 : (0, \pi) \leftrightarrow \mathbb{R}$ by $f_1(\theta) = \log(\tan(\theta/2))$ and $f_2 : (-\pi, 0) \leftrightarrow \mathbb{R}$ by $f_2(\theta) = \log(-\tan(\theta/2))$. Then

$$\Psi_{\beta}(\theta) = \begin{cases} f_1^{-1}(\beta f_1(\theta)) & \text{on } (0, \pi) \\ f_2^{-1}(\beta f_2(\theta)) & \text{on } (-\pi, 0) \\ \theta & \text{if } \theta = 0 \text{ or } \pi \end{cases}$$

This formula makes apparent the identity:

$$\Psi_{\beta_1 \beta_2} = \Psi_{\beta_1} \circ \Psi_{\beta_2}.$$

In this situation, the set of diffeomorphisms $\{\Psi_{\beta} \}$ is called a one parameter subgroup.

All one-parameter subgroups of the group of diffeomorphisms can be gotten this way. Their additive
form is more general. To put the $\Psi_\beta$’s in this form, it’s convenient to decompose the circle into four intervals between the four fixed points $\{0, \pi/2, \pi, 3\pi/2\}$ of $\Psi_\beta$. Then define $g(\theta) = \log(|\log|\tan(\theta/2)||)$ at all non-fixed points. Then:

$$\Psi_\beta(\theta) = \begin{cases} g^{-1}(\log(\beta) + g(\theta)), & \text{if } \theta \in ((k - 1)\pi/2, k\pi/2), \text{ some } k \\ \theta, & \text{if } \theta = k\pi/2, \text{ some } k. \end{cases}$$

The recipe generalizes like this: take any decomposition of the circle into a set of intervals $\{I_k = (\theta_k, \theta_{k+1})\}$. On each interval, take a bijective map $f_k : I_k \leftrightarrow \mathbb{R}$.

Then define:

$$\Psi_\alpha(\theta) = \begin{cases} f_k^{-1}(\alpha + f_k(\theta)), & \text{if } \theta \in I_k, \\ \theta, & \text{if } \theta = \theta_k, \text{ some } k. \end{cases}$$

For $\alpha$ infinitesimal, this diffeomorphism is given by the vector field:

$$v(\theta) = \frac{\partial}{\partial \alpha} f_k^{-1}(\alpha + f_k(\theta)) \bigg|_{\alpha=0} = (f_k^{-1})'(f_k(\theta)) = \frac{1}{f_k(\theta)}.$$

In this way, every vector field $v$ defines a one-parameter subgroup, as is well known from the theory of Lie groups.

Here’s an elegant example of this: start with the Fourier basis for vector fields $v_\psi(\theta) = \sin(n\theta), n \geq 2$. The zeros of these vector fields are the $2n$ points $\{\pi k/n, 0 \leq k < 2n\};$ these will be the fixed points of the corresponding one-parameter subgroups. By integrating, we solve for $f_k$ and it comes out:

$$f_k(\theta) = \frac{1}{n} \log \left| \tan \frac{n}{2} \theta \right|.$$
Sharon and Mumford

Figure 7. The shapes obtained by welding with \((2/n)\arctan(a \tan(n\theta/2))\) for \((n,a)\) equal to \((2, 2)\) (top left), \((2, 50)\) (top right), \((4, 2)\) (bottom left) and \((4, 50)\) (bottom right).

‘cigar-shaped’ blobs. One might have expected that these come from the one-parameter subgroup given by the vector field \(\sin(2\theta)\), but, as we saw, these shapes develop concavities. This is because they are symmetrical with respect to inversion \(z \mapsto 1/z\). Although the exact fingerprint for specific large eccentricity ellipses or long blobs is hard to compute exactly, the following argument gives fingerprints for one family of long blobs, as one verifies by welding. To construct this, we use 2 simple conformal maps which don’t quite match up and then we force them to match up! The exterior of a circle can be mapped to the whole plane minus the slit \([-r + r]\) by the conformal map \(w = (r/2)(u + 1/u)\). In this map, the exterior of a circle \(|u| \geq \lambda\), for \(\lambda\) slightly greater than 1, is carried to the exterior of an ellipse surrounding the slit, with width \(r(\lambda + 1/\lambda) \approx 2r\) and small height \(r(\lambda - 1/\lambda)\). Unfortunately, the conformal map to the interior of the ellipse is not given by elementary functions. But one can map the interior of the circle to the strip \(\text{imag}(w) < \pi\) by the map \(w = 2 \log ((1 + z)/(1 - z))\), and this maps the interior of the circle \(|z| \leq \mu\), for \(\mu\) slightly less than 1, to the interior of a cigar-shaped region inside this strip. This blob has height slightly less than \(2\pi\) and width 4 log \(((1 + \mu)/(1 - \mu))\). Both maps are illustrated in Fig. 9.

The images of these circles roughly match up if we require that \(2\pi = r(\lambda - 1/\lambda)\) and 4 log \(((1 + \mu)/(1 - \mu))\) = \(r(\lambda + 1/\lambda)\). We make an approximate fingerprint by mapping a point on the circle \(|z| = \mu\) to that point on the circle \(|u| = \lambda\) for which the real parts of the corresponding \(z\)-values are equal. This means:

\[
\text{Re} \left( \frac{r}{2} \left( \lambda e^{i\theta_1} + \lambda^{-1} e^{-i\theta_1} \right) \right) = \text{Re} \left( 2 \log \left( \frac{1 + \mu e^{i\theta_2}}{1 - \mu e^{i\theta_2}} \right) \right).
\]

or

\[
r \left( \frac{1}{2} + \frac{1}{\lambda} \right) \cos \theta_1 = \log \left( \frac{1 + \mu e^{i\theta_2}}{1 - \mu e^{i\theta_2}} \right), \quad \nu = \frac{2\mu}{1 + \mu^2}
\]
Figure 8. On the top left, internal and external conformal parametrization of the square. Top right, the fingerprint of the square; in the bottom, the functions $k(s, \theta)$ (left) and $h(s, \theta)$ (right) used in Sec. 3.2.2 to construct the shape from its fingerprint.

Figure 9. The construction of an explicit formula for the fingerprint of a long blob: on the left, (i) the red curve is an ellipse and its exterior is uniformized by $w = (r/2)(u + 1/u)$, (ii) the interior of the blue curve is uniformized by the map $w = 2 \log ((1+z)/(1-z))$ applied to a circle with radius slightly less than 1. The fingerprint on the right is made by matching points on these with the same real part and the yellow curve on the left is the result of welding with this fingerprint.

Simplifying, we get the formula for the fingerprints of long blobs, $\Psi_{\text{blob}}$ as:

$$\theta_1 = \arccos \left( \frac{\log \left( \frac{1 + v \cos \theta_2}{1 - v \cos \theta_2} \right)}{\log \left( \frac{1 + v}{1 - v} \right)} \right)$$

In this form, the fingerprint has high derivatives at 2 points, corresponding to the 2 ends of the blob and the interior conformal map takes 0 to the center of the blob. The same shape, however, is defined by $\Psi_{\text{blob}} \circ A$ for any Möbius map $A$. In particular, we get such a fingerprint if the interior map is chosen to take 0 to a point at
one end of the blob. Then the fingerprint will only have high derivatives at one point. With some experimentation, one finds a simple form for such a fingerprint:

\[
\Psi_{\text{blob}}(\theta) = \begin{cases} 
2\arctan \left( C_1 \sqrt{\log(1 + a \tan^2(\theta/2))} \right) & \text{if } \theta \in [-\theta_0, \theta_0] \\
2\arctan (\tan(\theta/2) + C_2 \text{sign}(\theta)) & \text{if } \theta \in (-\pi, \pi) - [-\theta_0, \theta_0]
\end{cases}
\]

where \( C_1, C_2 \) are chosen to make the above continuous with continuous derivatives.

We can use the formula for elongated blobs to illustrate the power of the group law in \( \text{Diff}(S^1) \). Suppose \( \Psi_1 \) and \( \Psi_2 \) are the fingerprints of 2 shapes. We can combine them in various ways using the fingerprints \( \Psi_1 \circ A \circ \Psi_2 \), for various Möbius maps \( A \). As \( A \) varies, the mode of combination varies. We take \( \Psi_1 = \Psi_{\text{blob}} \) to be the fingerprint of a suitable blob and \( \Psi_2 = \Psi_{\text{boom}} \) to be the fingerprint of a ‘boomerang’ shape computed by Schwarz-Christoffel. To combine them, we will first pick the constants \( a \) and \( \theta_0 \) in the blob fingerprint so that \( \Psi_{\text{blob}} \) is close to the identity over much of its domain, and has very large derivative at one point. Then we combine them with a rotation \( R \) inserted. In fact, to put the boomerang back in a fixed orientation, we show in Fig. 10 the shapes defined by \( R^{-1} \circ \Psi_{\text{blob}} \circ R \circ \Psi_{\text{boom}} \). The effect will be to create a new shape in which a blob is glued to the boomerang at a point depending on where this derivative is large.

Finally, we look at two more complex shapes. The first is a silhouette of a cat. For this we apply the Schwarz-Chr"{i}stoffel package in order to obtain \( \Psi(\theta) \). Hence \( \Psi(\theta) \), \( \Psi^{-1}(\theta) \) and \( \Psi^{-1}(\theta) \) involved in Eq. 13 are computed numerically. We reconstruct the shape using the first welding method. The result is shown in Fig. 11. Note again the close similarity of the computed \( \Gamma \) (right) to the original shape (left). Recall from Eq. 14 the way \( k \) and \( h \) (Fig. 11, bottom row) describe \( \Gamma \). In our current straightforward implementation we are limited in the size of the \((s, \theta)\)-grid we can solve for. This results in the minor distortions in \( k \) and \( h \) and the resulting \( \Gamma \).

The final example is the silhouette of the upper body of a person (see Fig. 12).

5. The WP Riemannian Metric on \( \mathcal{S} \)

5.1. The WP Norm on the Lie Algebra of \( \text{Diff}(S^1) \)

The Lie algebra of the group \( \text{Diff}(S^1) \) is given by the vector space \( \text{vec}(S^1) \) of smooth vector fields on the circle: \( v(\theta) \Delta \theta \) where \( v(\theta + 2\pi) = v(\theta) \). In general, the adjoint action of a group element \( g \in G \) is the linear map from \( \text{Lie}(G) \) to itself induced by the conjugation map \( h \mapsto g^{-1} \circ h \circ g \) from \( G \) to itself. Explicitly, this maps \( v \in \text{vec}(S^1) \) to \( (v \circ g)/g' \), i.e. \( ad_g(v) = (v \circ g)/g' \).

We can expand such a \( v \) in a Fourier series \( v(\theta) = \sum_{n=-\infty}^{\infty} a_n e^{i n \theta} \) (where \( \overline{a_n} = a_{-n} \)). The Weil-Petersson norm on \( \text{vec}(S^1) \) is defined by:

\[
||v||_{WP}^2 = \sum_{n=2}^{\infty} (n^3 - n)|a_n|^2.
\]

The null space of this norm is given by those vector fields whose only Fourier coefficients are \( a_{-1}, a_1 \) and \( a_2 \), i.e. the vector fields \( (a + b \cos(\theta) + c \sin(\theta)) \Delta \theta \), which are exactly those tangent to the Möbius subgroup \( \text{PSL}_2(\mathbb{R}) \), i.e. in its Lie algebra \( \text{psl}_2(\mathbb{R}) \).

The motivation for this particular definition is the fact that, for all \( \phi \in \text{PSL}_2(\mathbb{R}) \) and \( v \in \text{vec}(S^1) \), one can verify that

\[
||ad_\phi(v)||_{WP} = ||v||_{WP}.
\]

5.2. Extending the Metric to \( \text{Diff}(S^1)/\text{PSL}_2(\mathbb{R}) \)

Riemannian metrics on coset spaces \( G/H \) which are invariant by all left multiplication maps \( L_g : G/H \to G/H, g \in G \) are given by norms \( || \cdot || \) on the Lie algebra of \( G \) which are zero on the Lie subalgebra of \( H \) and which satisfy \( ||ad_g(\cdot)|| = ||\cdot|| \) for all \( h \in H \). Here the norm on the tangent space \( T_{\phi}(G/H) \to G/H \) at any \( gH \) is gotten from the norm on the Lie algebra via the isomorphism

\[
DL_g : \text{Lie}(G)/\text{Lie}(H) = T_{eH,G/H} \to T_{gH}
\]

given by the derivative of \( L_g \) at the identity \( e \) of \( G \). In particular, this applies to \( \text{Diff}(S^1) \) and \( \text{PSL}_2(\mathbb{R}) \). Because \( \text{Diff}(S^1)/\text{PSL}_2(\mathbb{R}) \cong \mathcal{S} \), we have now constructed a homogeneous Riemannian metric on \( \mathcal{S} \) also.

Next let’s translate this into concrete terms. Take any path \( \Psi(t, \theta) \) in \( \text{Diff}(S^1) \), where \( t \in [0, t_0] \subset \mathbb{R} \) and \( \Psi(t, \theta + 2\pi) = \Psi(t, \theta) + 2\pi \). The tangent vectors to this path are given by \( \frac{\partial \Psi(t, \theta)}{\partial t} = \Psi(t, \theta) \) or, translated back to the Lie algebra using \( DL^{-1} \), by
Ψ(t, θ)/Ψ(t, θ). We expand the tangent vector at every \( t \geq 0 \) by its Fourier series in \( \theta \):

\[
\Psi(t, \theta)/\Psi(t, \theta) = \sum_{n=-\infty}^{\infty} a_n(t)e^{in\theta}, \quad (25)
\]

where \( a_{-n}(t) = \overline{a_n(t)} \) because the vector field is real. Its Weil-Petersson norm is then given by

\[
\|\Psi(t, \theta)/\Psi(t, \theta)\|_{WP} \doteq \sum_{n=2}^{\infty} |a_n(t)|^2(n^3 - n) \quad (26)
\]
and the length of the path is by definition:
\[ \int_0^t \sqrt{\sum_{n=2}^{\infty} |a_n(t)|^2(n^3 - n)} dt. \]

It is a wonderful fact that all sectional curvatures of the Weil-Petersson norm are non-positive (Bowick and Lahiri, 1988). Because of this, it is to be expected that there is a unique geodesic joining any two shapes \( \Gamma_1, \Gamma_2 \in S \). Because minimizing energy and length are equivalent, these geodesics are the solutions of the following minimization problem

\[ \min_{\psi(t, \theta), t_0} \int_{t=0}^{t_0} \sum_{n=2}^{\infty} |a_n(t)|^2(n^3 - n) dt, \]  

where \( \psi(0, \theta) \) and \( \psi(t_0, \theta) \) are the diffeomorphisms corresponding to the two given end-point shapes.
6. Calculating the Geodesics

We solve for the geodesics \( \{ \Psi(t, \theta) \}_{t \in [0,1]} \), where \( \Psi(t, \theta) \in \text{Diff}(S^1) \forall t \in [0,1] \), parameterized by ‘time’ \( t \) between the two given end-point shapes \( \Psi_0 = \Psi(0, \theta) \) and \( \Psi_1 = \Psi(1, \theta) \). The length of the geodesic between each two given end-point shapes is obtained by minimizing the Weil-Petersson norm

\[
\int_0^1 ||\Psi(t, \theta)/\Psi_0(t, \theta)||_{WP} dt, \tag{28}
\]

where \( \Psi_0 \) and \( \Psi_1 \) are the diffeomorphisms (fingerprints) corresponding to the two given end-point shapes (see Sec. 5.2).

Minimizing the norm in Eq. (28) is equivalent to minimizing the energy

\[
E(\Psi_0, \Psi_1) = \int_0^1 \sum_{n=2}^{\infty} |a_n(t)|^2 (n^2 - n) dt, \tag{29}
\]

(cf. Sec. 5.2), where

\[
\Psi(t, \theta) = \sum_{n=-\infty}^{\infty} a_n(t)e^{in\theta}. \tag{30}
\]

We discretize \( t \in [0,1] \) into \( M \) homogenously spaced points \( t_s = s/M, u = 0, 1, 2, \ldots, M \), and we discretize \( \theta \in [-\pi, \pi] \) into \( N \) homogenously spaced points \( \theta_k = -\pi + \frac{2\pi k}{N}, k = 0, 2, \ldots, N - 1 \).

We will always choose \( N = 2^m \) and \( M = 2^n \) for suitable \( n, m \). We discretize the geodesics using a \((k, u)\)-grid into \( \{ \Psi(t_s, \theta_k) \}_{s,u} \), where \( k = 0, 2, \ldots, N-1 \) and \( u = 0, 2, \ldots, M \). Both \( \Psi_0 = \{ \Psi(t_s, \theta_k) \}_k \) and \( \Psi_1 = \{ \Psi(t_s, \theta_k) \}_k \) are fixed as the end-point diffeomorphisms. In addition it is convenient for computing the energy (Eq. 29) to discretize the parameter \( t \) in the integral using also a shifted \( u \)-grid, namely an \( s \)-grid for which \( t_s = \frac{1}{2M} + \frac{s}{M}, s = 1, 2, \ldots, M \). We denote \( t_{s_\pm} = t_s - \frac{1}{2M} \) and \( t_{s_+} = t_s + \frac{1}{2M} \), so that the grids \( s_- \) and \( s_+ \) coincide with points of the \( u \) grid.

We can therefore discretize

\[
\Psi_0(t_s, \theta_k) \approx \frac{1}{2} \left( \frac{\Psi(t_{s_+}, \theta_k+1) - \Psi(t_{s_-}, \theta_{k-1})}{4\pi/N} + \frac{\Psi(t_{s_-}, \theta_{k+1}) - \Psi(t_{s_+}, \theta_{k-1})}{4\pi/N} \right), \tag{31}
\]

and

\[
\Psi_1(t_s, \theta) \approx \frac{\Psi(t_{s_+}, \theta) - \Psi(t_{s_-}, \theta)}{1/M}, \tag{32}
\]

thus obtaining the following discretization:

\[
\Psi_s(t_s, \theta_k) \approx \frac{MN}{8\pi} \left( \Psi(t_{s_+}, \theta_k) - \Psi(t_{s_-}, \theta_k) + \Psi(t_{s_-}, \theta_{k+1}) - \Psi(t_{s_+}, \theta_{k-1}) \right) \tag{33}
\]

To compute the geodesics \( \{ \Psi(t_s, \theta_k) \}_{s,u} \), we will therefore minimize the discretized version of Eq. 29

\[
\tilde{E}(\tilde{\Psi_s}, \tilde{\Psi_1}) \equiv \sum_{s=1}^{M} \sum_{n=2}^{N-2} |a_n(t_s)|^2 (n^2 - n). \tag{34}
\]
where \( s = 1, 2, \ldots, M \) and \( k = 0, 1, \ldots, N - 1 \) we have the discrete Fourier transform

\[
\psi_{1}(t_s, \theta_k) = \frac{1}{N} \sum_{n=0}^{N/2} a_n(t_s) e^{2\pi i n k / N}, \quad a_{N-n}(t_s) = \overline{a_n(t_s)}.
\]

(35)

We denote \( E_{0,1} \equiv \tilde{E}(\tilde{\psi}_0, \tilde{\psi}_1), \psi_{t,u} \equiv \psi(t_s, \theta_k), \) and \( \psi_{t,u} \equiv \psi(t_s, \theta_k). \)

6.1. Direct Computation of the Energy Gradient \( \partial \tilde{E}_{0,1} / \partial \psi_{t,u} \)

For introducing numerical, iterative minimization of the energy \( E_{0,1} \) it is useful to develop an efficient
formula for directly computing its gradient $\partial \tilde{E}_{0,1}/\partial \Phi_{k,n}$. To obtain this we define

$$\hat{w}_k = \tilde{k}^3 - \tilde{k}, \quad \text{where } \tilde{k} = \min(k, N - k). \tag{36}$$

We then define $\{w_l\}_{l=0}^{N-1}$ to be the discrete Fourier transform of $\{\hat{w}_l\}_{l=0}^{N-1}$. That is

$$w_l = \sum_{k=0}^{N-1} \hat{w}_k e^{-2\pi i kl/N}. \tag{37}$$
Denoting
\[ f_{i,j}(\Psi) = \Psi_i(t_j, \theta_k) \]
we can rewrite \( \tilde{E}_{0,1} \), up to a multiplicative constant in the following way
\[ \tilde{E}_{0,1} = \sum_{i,j,s} w_{i-j} f_{i,j}(\Psi) f_{j,i}(\Psi). \]
(by simply substituting Eq. 37 and Eq. 38 in Eq. 39 to satisfy Eqs. 34 and 35.)
Hence
\[ \frac{\partial \tilde{E}_{0,1}}{\partial \Psi_{k,u}} = 2 \sum_{i,j,s} w_{i-j} f_{i,j}(\Psi) \frac{\partial f_{j,i}(\Psi)}{\partial \Psi_{k,u}}. \]

Note that \( \frac{\partial f_{i,j}(\Psi)}{\partial \Psi_{k,u}} \) for every entry \((k, u)\) is only different from 0 in 6 of its \((j, s)\) entries. That is, when \( s_u = u \) or \( s_u = u \), and \( j = k - 1, k, k + 1 \). Denoting \( u_{+} = u \pm \frac{\sigma}{M} \), we can break Eq. 40 into six sums, each of which is efficiently computed through a multiplication of a full \( N \times M \) matrix of the form \( w_{i-j} \) with a sparse \( N \times M \) matrix of the form \( f_{i,j} \).

6.2. Choosing a Representative Fingerprint in Each Shape Coset

Recall that every shape is represented by an equivalence class of diffeomorphisms, namely a coset in \( \text{Diff}(S^1) / \text{PSL}_2(\mathbb{R}) \). This creates ambiguities in the choice of fingerprint \( \Psi \) of each shape that need to be resolved before making a numerical computation of the geodesic between two shapes. The most natural way to obtain a canonical representative of each coset is to choose the unique diffeomorphism in that coset which fixes three prescribed values (angles).

Specifically, suppose the coset corresponding to a shape is given by the subset
\[ \{ \Psi \circ A | \Psi \in \text{Diff}(S^1), A \in \text{PSL}_2(\mathbb{R}) \} \subset \text{Diff}(S^1). \]

For any \( \Psi \) we can find a unique \( A \) so that \( \Psi \circ A \) fixes three prescribed angles, thus obtaining a unique fingerprint representation \( \Psi \circ A \) for the coset \( \Psi \circ A \).

Using Driscoll’s Schwarz-Christoffel software package we compute a fingerprint \( \Psi \) for each shape, such that \( \Psi(-\pi) = -\pi \). We then compose \( \Psi \) with \( A \in \text{PSL}_2(\mathbb{R}) \), denoting \( \tilde{\Psi} = \Psi \circ A \) such that \( \tilde{\Psi}(-\pi) = -\pi \), \( \tilde{\Psi}(\alpha) = \alpha \) and \( \tilde{\Psi}(\beta) = \beta \), where \( \alpha = -\pi/4 \) and \( \beta = +\pi/2 \). We obtain this by taking
\[ A(\theta) = 2 \cdot \arctan(a + b \tan(\theta/2)), \]
which satisfies \( A(-\pi) = -\pi \) for every \( a, b \in \mathbb{R} \), and fix \( a \) and \( b \) so that \( A(\alpha) = \Psi^{-1}(\alpha) \) and \( A(\beta) = \Psi^{-1}(\beta) \). That is, by Eq. 41 we solve for \( a \) and \( b \) such that
\[ a + b \tan \frac{\alpha}{2} = \tan \left( \frac{\Psi^{-1}(\alpha)}{2} \right), \]
\[ a + b \tan \frac{\beta}{2} = \tan \left( \frac{\Psi^{-1}(\beta)}{2} \right). \]

6.3. Minimizing the Energy \( \tilde{E}_{0,1} \)

As we have seen in the previous section, we may assume that the fingerprints \( \Psi_0 \) and \( \Psi_1 \) of the endpoint shapes satisfy \( \Psi_0(-\pi) = \Psi_1(-\pi) = -\pi \), \( \Psi_0(\alpha) = \Psi_1(\alpha) = \alpha \) and \( \Psi_0(\beta) = \Psi_1(\beta) = \beta \). We then minimize \( \tilde{E}_{0,1} \) (see Eq. 39) with all the intermediate diffeomorphisms along the geodesic keeping the three angles \(-\pi, \alpha \) and \( \beta \) fixed. That is, we minimize \( \tilde{E}_{0,1} \) with respect to the scalar variables \( \Psi(t_u, \theta_k) \), for \( u = 1, 2, \ldots, M - 1 \) and \( k = \{ 0, 1, \ldots, N - 1 \} \), \( k \neq 0, 3N/8, 3N/4 \). For these remaining three values of \( k \) corresponding to \( \theta = -\pi, \alpha, \beta \) we keep the other values fixed while the values of the diffeomorphisms fixed through the minimization, i.e. \( \Psi(t_u, \theta_k) = \Psi_0(t_u, \theta_k) = \Psi_1(t_u, \theta_k) = -\pi, -\pi/4, \pi/2 \) for \( u = 1, 2, \ldots, M - 1 \).

We start with \( M = 8 \) and \( N = 64 \), and set as the initial approximation for all intermediate diffeomorphisms a fingerprint of the circle shape. Specifically we set
\[ \Psi(t_u, \theta_k) = \theta_k, \]
for \( u = 1, 2, \ldots, M-1 \) and \( k = 0, 1, \ldots, N-1 \).

We then minimize \( \tilde{E}_{0,1} \) by gradient descent, starting at the current approximation to the solution (the initial approximation from Eq. 43), and minimizing the energy along the direction of the gradient (using the ‘line search’ method). In practice, we use the Matlab optimization function \texttt{fminunc}. We then take this minimizing solution for \( (N = 64, M = 8) \), and interpolate it in the variables \( \{ \theta_k \}_{k=0}^{N-1} \) to be an initial approximation for the higher resolution case, \( (N = 128, M = 8) \), and minimize again the same way using \texttt{fminunc} . We interpolate onto even higher resolution one more time to solve for \( (N = 256, M = 8) \).
7. **Examples of Geodesics**

We present 4 geodesics computed by the algorithm above (Figs. 13-16). Each of these figures should be read from left to right and top to bottom, starting at the top-left and ending at the bottom-right. Note the strong tendency to revert to shapes nearly equal to circles in the middle; this is a reflection of the fact the space of shapes is negatively curved in this metric.

8. **Summary and Conclusions**

We introduce a metric space-of-shapes that arises from conformal mappings, through the mathematical theory of complex analysis. In this space, the shortest path between each two shapes is unique, and is given by a geodesic connecting them, providing a path for morphing between them. Every shape is represented in this space by an equivalence class of “fingerprints” each of which is a diffeomorphism of the unit circle to itself. We solved the welding problem to allow moving back and forth between shapes and this space-of-shapes, thus allowing the continuation of the research of shapes within this space. Indeed, our next step will be to compute the geodesics between *many* different* shapes. We expect these to reflect the appeal of the structure-preserving properties of conformal mappings, and to be very relevant to the comparison and classification of shapes.

**Notes**

1. To be clear, by a shape we usually mean a smooth simple closed curve in the plane, although sometimes we mean the curve plus its interior.
2. For example, we have ‘Minkowski addition’ of shapes but this addition cannot have inverses because it always makes a shape bigger.
3. The reason for the notation $PSL_2(\mathbb{R})$ is that conjugating by $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ takes $2 \times 2$ real matrices to the $2 \times 2$ complex matrices $\begin{pmatrix} a & b \\ c & d \end{pmatrix}$, so the same notation is used for both groups of matrices.
4. Smoothness of $\Gamma$ is not required for Riemann’s result.
5. Recall that an element in a coset space $G/H$ is a subset $gH = \{g \cdot h \mid h \in H\}$ of $G$.
6. In fact, it is a homeomorphism and is nearly unique: if $F$ is one solution, then $aF + b$ are all the other solutions.
7. For the modifications used in the expression for the exterior, see (Driscoll and Trefethen, 2002), p. 52.
8. In fact, if $b = a \cdot \tan(\theta_0/2)$, $c = 1 + a \cdot \tan^2(\theta_0/2)$, then $C_1 = \sqrt{\log c/b}$ and $C_2 = (\log c/e), c + 1)/b$.
9. Because the space is infinite dimensional, this requires proof and this aspect of the metric does seem to have been discussed in the literature.
