Abstract

Sophisticated and highly coordinated mechanisms regulate histone methylation during development. In a diseased state this can give rise to multi-organ system congenital disorders such as Kabuki syndrome. The *Caenorhabditis elegans* animal model provides unique control in recapitulating genetic conditions relevant to disease states, as its genes are widely homologous to humans' and its cellular development is well characterized. With this in mind, an experimental approach was designed to selectively depletion the key epigenetic regulators SET-16 or UTX-1, homologous in function to human KMT2D and KDM6A, respectively, malfunctions in which underly Kabuki syndrome. The auxin inducible degron (AID) system was shown to reliably induce targeted proteasomal degradation of SET-16 and UTX-1 resulting in changes to gene expression regulated by these factors, identified through transcriptomic analysis. The extent of auxin-induced depletion depended on both the concentration of auxin applied and the amount of time the animals were exposed. Early depletion of either SET-16 or UTX-1 consistently reduced the number of oocytes present, as well as overall fecundity. Genomic analysis indicates common changes in the expression patterns of at least 390 genes between both depletion scenarios, providing a list of potential genetic candidates for targeted treatment of Kabuki syndrome.

Acknowledgments

It is important to note that this project would not have been possible without funding through the Roya Kabuki Program and the aid of its collaborators.

I would like to extend my appreciation to Dr. Maxwell Heiman, who served as my research instructor and mentor, for both supplying the strains and devoting the time and attention to teaching me how to work with *C. elegans* in the laboratory, as well as how to perform a multitude of tasks that were critical to performing experiments and accumulating the necessary data for this project. I could not have accomplished much with regard to the following thesis project without his patience and devotion to teaching aspiring scientists, especially given the global circumstances of early 2020. The access I was given to state of the art technologies and materials was truly a privilege and the techniques I was taught will aid my future research for decades to come.

Also, I would like to offer a special thank you to both Dr. Christina Hung and Dr. Alan Jiao for their time and patience. Everything I know with regard to proper handling of RNA samples and purification techniques I credit to Dr. Hung. Her encouragement was absolutely necessary when attempting to master such a delicate process.

Dr. Jiao had no obligation to allow me to shadow him as he worked in order to learn from his techniques, but he happily volunteered his time and attention. His passion and drive is something that I fully intend to mirror throughout my career, and I greatly appreciate the first hand lessons that he showed me.

Chapter I.

Introduction

Kabuki syndrome is a relatively unfamiliar condition in the modern medical field. Those diagnosed face a multitude of hurdles through life. Symptoms such as congenital heart defects, mental impairment, and immune deficiency are typically associated with this genetic disorder. Therefore, establishing a firm grasp on the underlying biological mechanisms is critical to developing more effective diagnostic protocols and ameliorative treatments. While it was first officially described in 1981, molecular data underlying the syndrome was only uncovered as recently as 2010 [Ng et al., 2010]. This is attributed to a variety of factors that make Kabuki syndrome difficult to clinically diagnose. First, the condition is thought to be somewhat rare, occurring in fewer than 1/32,000 [Cheon et al., 2015]. However, given the scarcity of diagnostic methods population statistics are subject to debate. Second, phenotypes typical of the condition, such as characteristic physiognomy (lateral sparseness of the eyebrow and eversion of the lower eyelid; prominent ears with a depressed nasal tip; etc.), tend to lose conspicuousness as the children age and grow [Matsumoto and Niikawa, 2003]. This means that unless identified early, the condition may go undetected into adulthood. Lastly, Kabuki syndrome can arise from various mutations in the *kmt2d* gene and sometimes in the *kdm6a* gene [Cocciadiferro et al., 2018]. However, these mutations are most often *de novo* which results in a lack of family history and a large amount of heterogeneity between cases, compounding the difficulties associated with recognizing the syndrome by phenotype alone.

Because information regarding the molecular genetics of this condition were virtually non-existent until only a decade ago, much remains to be done in terms of exploring the pathology and etiology of this disease. Through whole exome sequencing it was determined that *kmt2d* is the most frequently mutated gene in cases of Kabuki syndrome, with only a small percentage of patients possessing mutations in *kdm6a* [Ng et al., 2010]. KMT2D, histone-lysine *N*-methyltransferase 2D, belongs to a family of histone H3 lysine 4 (H3K4) methyltransferases that play various roles in regulating gene expression during development. This family is largely conserved, with homologs discovered in the genomes of invertebrates such as *Drosophila* and even in fungi, such as yeast [Froimchuk et al., 2017]. KDM6A, histone-lysine demethylase 6A, belonging to a family of histone H3 lysine 27 (H3K27) demethylases, claims a similar degree of conservation across species [Maures et al., 2011]. Fortunately, these genetic similarities allow for the use of well-characterized model organisms to more closely study the role histone methylation plays during cellular development, as well as to understand how mutations that affect chromatin remodeling can result in such a plethora of symptoms across multiple organ systems, typical of Kabuki syndrome.

Understanding the effect reduced activity by KMT2D or KDM6A has on development will be useful in determining the pathogenic mechanisms underlying Kabuki syndrome. Determining the importance and specificity of histone methylation by KMT2D and KDM6A interactions throughout development will serve to address several questions that persist regarding Kabuki syndrome: where and at what point in development must a mutation occur? And, why are some, indeed most, organ systems effected, but not all?

In order to address these points of interest, *Caenorhabditis elegans* has been employed as an animal model for either *kmt2d* or *kdm6a* haploinsufficiency. In order to experimentally determine the minimum threshold for reduced expression to produce characteristic phenotypes, an auxin inducible degron (AID) system has been engineered to selectively deplete products of the homologous genes *set-16* (*kmt2d*) or *utx-1* (*kdm6a*) in either somatic or germ-line tissues [Zhang et al., 2015]. This system is advantageous in that it allows for the conditional depletion of a specific protein product in defined tissues, and this study shows the extent of depletion can be modulated based on the concentration of auxin. Importantly, this system is reversible—removing auxin restores homeostatic protein levels and activity. Having temporal and spatial control of KMT2D/KDM6A levels allows for the selective manipulation of target histone methylation during different windows of development and within different tissue types. This is critical to understanding the timetable of Kabuki syndrome occurrence and progression. Tissue specificity also makes it possible to address organ systems in isolation, parsing out symptoms that are a direct result of the developmental disorder, versus the result of indirect interactions with other affected organs.

Despite its potential, the AID system is still a relatively new tool and much remains to be tested and refined regarding its application. While initial studies that employed AID have been carried out in various animal models ranging from fruit flies to zebrafish, to date the degree of control in manipulating protein levels has not been fully addressed. Previous studies focused on showing that endogenous protein depletion is efficient, rapid, and reversible but did not fully evaluate to what extent depletion can be

manipulated [Nishimura et al., 2009; Morawska et al., 2013; Zhang et al., 2015; Daniel et al., 2018; Sathyan et al., 2019].

As stated, Kabuki syndrome is a multi-organ system congenital disorder caused by *de novo* mutations in either *kmt2d* (*set-16*) or *kdm6a* (*utx-1*) resulting in the haploinsufficient expression of KMT2D/SET-16 or KMD6A/UTX-1, respectively. Yet, how the transcriptome responds to partial depletion of these factors remains to be studied in depth. The following series of experiments demonstrate that exposure to progressively elevated concentrations of auxin produces titratable depletion of AID-tagged SET-16 and UTX-1 in somatic and germline tissues, mirroring the reduced gene dosage effects in Kabuki syndrome. Transcriptomic analysis was used to evaluate the genomic response to reduced levels of SET-16 or UTX-1 throughout early embryonic development. Results demonstrate that some genes follow a trend in changed expression proportional to elevating levels of auxin, while others produce a more exaggerated trend, reminiscent of a binary, on-or-off response.

Kabuki Make-Up Syndrome

History and Discovery

While the name "Kabuki-makeup syndrome" was officially coined in 1981, harkening to the traditional make-up used in Kabuki theater, the condition was observed and documented in the medical literature as far back as 1967 [Niikawa et al., 1981]. It was first described by the Japanese pediatrician Dr. Norio Niikawa, who reportedly encountered multiple young patients as a clinician, all presenting the same or similar unique features (Figure 1). In 1968, a different, independent, group of researchers led by Dr. Yoshikazu Kuroki examined five patients all exhibiting the same unique set of symptoms [Kuroki et al., 1981]. These parallel findings led both teams of researchers to independently conclude that their patients possessed a previously undescribed condition. Dr. Niikawa initially presented his findings in 1979 to the Japanese Dysmorphology Conference, before coordinating with Dr. Kuroki and establishing the condition as "Kabuki make-up syndrome," despite reservations by editors at the *Journal of Pediatrics* that the name may be too unfamiliar for western scientists [Matsumoto and Niikawa, 2003]. Hence the more common and simpler term "Kabuki syndrome" used predominantly in western literature.

Etiology and Disease Progression

The most common features of this disease are dysmorphic facial appearance (sparseness of the lateral 2/3^{rds} of the brow, long palpebral fissures, upturning or eversion of the outer 1/3rd of the lower eyelid, broad/depressed nasal tip, and large, protruding

ears), skeletal anomalies (scoliosis, stunting, joint laxity, short fifth finger and phalanges), dermatoglyphic abnormalities (presence of finger-tip pads, finger-tip ulnar loop patterns), and both mental and growth retardation [Matsumoto and Niikawa, 2003]. These have been established as the five cardinal diagnostic criteria in identifying the syndrome. However, this method for diagnosis is flawed in that no two cases of Kabuki syndrome are identical, and these symptoms may not all be present or visually apparent in every patient. Also, these phenotypes tend to change or evolve over time, meaning that unless the condition is observed early the cardinal symptoms may no longer be obvious. In such a scenario, it is a short leap to imagine that a later diagnosis may exclusively focus on the individual symptoms, overlooking the entire syndrome. Much of the blame for difficulties in unraveling this disease, or improving screening methods, rests with the fact that the majority of cases are the result of spontaneous *de novo* mutations that introduce either a frameshift, missense or nonsense mutation within the *kmt2d* gene [Ng et al., 2010; Cocciadiferro et al., 2018]. A missense mutation or frameshift may alter the protein structure of KMT2D or its associated complex, whereas an early stop codon can halt expression of the protein entirely. Patients with similar mutations may exhibit similar or divergent phenotypes. It remains unclear if differences in disease presentation are caused by the type of mutation within the gene, at what point during embryo development that mutation occurred, or other environmental or genetic factors [Cocciadiferro et al., 2018].

Current Therapies

Initially, it was believed that the condition must be regional and is likely much less common outside of Japan, but upon further study, it was soon realized that the rate of

occurrence is largely consistent across all populations, albeit still rare [Cheon and Ko, 2015]. It is for this reason that data on the genealogy and molecular physiology of Kabuki syndrome was only first published less than a decade ago. As a consequence, there are tragically few effective therapies for this condition. Because Kabuki syndrome is characterized by congenital deformities across multiple organ systems there is no one therapy that could address all of the symptoms a patient is likely to possess. This is why it is necessary to establish an intimate understanding of the associated mechanisms that are affected by *kmt2d* or *kdm6a* mutations. There is a consensus that therapies designed to target a common denominator mechanism (if there is one), should claim primary focus with regard to research and the development of treatments [Aref-Eshghi et al., 2017].

Caenorhabditis elegans

History and Justification

C. elegans is a soil dwelling nematode. They can be isolated from decaying vegetable or fruit matter and detritus, where they feed off of resident bacteria [De Ley et al., 2011]. It was first put forward as an animal model by Sydney Brenner, in 1963, via a letter to the chairman of the Medical Research Council's Laboratory of Molecular Biology. He reasoned that an approach like that used in studies of bacteria and phages was needed to attack more subtle or mechanistic questions regarding the form and function of the nervous system, gene regulation during development, and other complex metazoan processes [Brenner et al., 1973]. *Drosophila* was already established as an effective animal model by the time of Brenner's letter, but he argued that even they are too large and complex. Therefore, he proposed that a multicellular organism should maintain as much simplicity as possible as is represented in prokaryotic systems. From this, nematodes became a leading candidate. Initially, Brenner suggested the species *C. briggsae*, but later decided on *C. elegans* for technical reasons—mainly for quality of growth in a laboratory environment [Corsi et al., 2015].

Biology, Ecology, and Lifecycle

The nematode is a relatively simple animal, with a rapid life cycle and rudimentary body form (Figure 2). Because they naturally subsist on bacteria in the wild, *C. elegans* can be easily maintained on an agar plate seeded with a lawn of laboratory strain *Escherichia coli*. These hardy organisms can survive starvation for up to six

months by entering what is referred to as a ‘dauer’ state, and can even survive being frozen for long-term storage [Brenner et al., 1973]. Obviously, these are valued traits in an animal model, due to the time constraints and typically harsh environment associated with being in a laboratory. As previously mentioned, other *Caenorhabditis* species were considered for a model, but *C. elegans* grows the healthiest between 20-25˚C (typical laboratory room temperature standard) making it convenient for housing large populations in a single facility [Corsi et al., 2015]. *C. elegans* are developmentally fixed in that the wild-type growth rate does not vary between specimens. This makes the animal a uniquely versatile model for testing molecular mechanisms that are conserved across more complex, less predictable, animals. Perhaps even more advantageous, phenotypes have been catalogued for almost every gene in the *C. elegans* genome [Culetto and Sattelle, 2000]. As for their anatomy, the entire animal is composed of only 959 somatic cells, wherein roughly one-third are neurons. From this simplicity, it was possible to characterize the fate of every embryonic cell starting at fertilization [Sulston et al., 1988]. Another useful advantage to using this animal as a model is their characteristically short lifecycle—taking only about 4-5 days from embryo fertilization to fertile adult. Adding to this, *C. elegans* reproduce by self-fertilization and many phenotypes adhere to a strict Mendelian pattern of inheritance, meaning that mutant stocks can be readily established and maintained [Brenner et al., 1973; Corsi et al., 2015]. Because every cell lineage is known, these animals are useful models to evaluate the effects a particular gene may have on any cell population, through any known mechanism. This is ideal for modeling cancers and developmental disorders, as

researchers are able to watch the effects of altered gene expression during development, in real time, within a whole organism.

Previous Applications

Because of the simplicity, versatility and ease of handling that *C. elegans* allows, this animal has been instrumental in filling informational gaps resulting from the use of more complex organisms. One such example involves a mutagenesis experiment that uncovered a set of genes which governed phagocytosis of apoptotic cells in early embryo development. From their observations, and further genetic studies, researchers identified mechanisms for programmed cell death, which, prior to that experiment, was a process believed to be conferred largely by necrosis [Hedgecock et al., 1983; Ellis and Horvitz et al., 1986]. Another example includes a study that discovered the effectiveness of double-stranded RNA interference (dsRNAi) as a method for controlled depletion of gene products [Fire et al., 1998]. To this day dsRNAi is a staple method used by geneticists and molecular biologists the world over. Since Brenner first made the argument for *C. elegans*' usefulness in the lab, many studies have been carried out using this animal model. Genes that regulate lifespan have been discovered in *C. elegans* [Kenyon et al., 1993] and this animal even served as the first whole-organism in which Channelrhodopsin-2 was demonstrated to be effective in eliciting controlled neuronal activation [Nagel et al., 2005]. The advantages associated with this animal model are such that, in 2002, Sydney Brenner and his colleagues, H. Robert Horvitz and John E. Sulston, were awarded the Nobel Prize in Physiology or Medicine for their work on genetic regulation of organogenesis and mechanisms of apoptosis.

Overview of Function and Patterns of Expression

Chromatin refers to the basic structural organization of DNA within a eukaryotic cell's nucleus, consisting mainly of tightly packed proteins known as core histones, along with various scaffold-like proteins that provide structural support and kinetic access to transcription-regulating enzymes [Moore et al., 2012]. The nucleosome is the major unit of chromatin, formed from an octamer complex of two of each of the histone core proteins H2A, H2B, H3 and H4, around which ~147 base pairs of DNA are wrapped [Kouzarides et al., 2007]. Each histone subunit possesses an exposed NH_2-terminal tail that can be modified, recruiting transcription-regulating enzymes to the regions of wrapped DNA via patterns of methylation, acetylation and phosphorylation at different amino residues. Various studies using mass spectroscopy and antibody staining have identified key patterns associated with active gene expression and maintenance, as well as gene silencing [Heintzman et al., 2007; Kouzarides et al., 2007; Moore et al., 2012]. Importantly, different extents of methylation have been identified that are unique to specific amino acids: lysines (K) can be marked by either mono-, di-, or trimethylation while arginines (R) only exhibit mono- and dimethylation, for example. Each of these states represent a different form of transcriptional readiness, whereby mono- and dimethylation of lysine is typically associated with enhancer priming, while trimethylation is often an indication of promoter activation [Ruthenburg et al., 2007; Wang et al., 2016]. This is with regard to regulation of developmental and lineage determining genes in eukaryotic cells, but these methylation patterns vary between cell

types and are also believed to play intimate roles in epigenetic regulation after development [Heintzman et al., 2007; Kouzarides et al., 2007; Ruthenburg et al., 2007]. Methylation of lysine residues is carried out by a family of enzymes known as lysine methyltransferases, or KMTs. In humans, KMT2D, often referred to as Mixed Lineage Leukemia 4 (MLL4, also sometimes referred to as MLL2 in some older literature), has been identified as a key regulator of gene expression during development [Lee et al., 2013; Yan et al., 2018]. KMTs in humans exist in the COMPASS/MLL family of complexes, but because of its known role in early development and indications that malfunction of this particular member leads to developmental disorders such as Kabuki syndrome, KMT2D of COMPASS/MLL4 will be the primary subject for discussion [Froimchuk et al., 2017; Cocciadiferro et al., 2018]. An important subunit of the COMPASS/MLL4 complex, KDM6A, or lysine demethylase 6A, has also been shown to play a critical role in promoting stability of the overall complex, as well as in preparing chromatin for KMT2D activity [Wang et al., 2017]. Malfunctions in KDM6A have also been implicated in cases of Kabuki syndrome, although less commonly [Cocciadiferro et al., 2018]. KMT2D specifically deposits methyl groups on the 4th lysine of the H3 core histone, or H3K4 site. As previously mentioned, these modifications can include H3K4me1, H3K4me2, and H3K4me3 and are indicators of enhancer activation (H3K4me1, H3K4me2) and promoter activation (H3K4me3) [Ruthenburg et al., 2007; Lee et al., 2013; Wang et al., 2016]. KDM6A, also commonly referred to as UTX-1, or simply UTX, is a primary H3K27me-1, or demethylator that has been shown to play an important conformational role for KMT2D activity [Zhang et al., 2016; Wang et al., 2017]. However, the exact kinetics of this interaction are not yet well understood. For

example, it has been shown in a *C. elegans* model that KDM6A regulates cellular development and normal growth regardless of its demethylase activity [Vandamme et al., 2012]. It is also required for the recruitment of the H3K27 acetyltransferase (H3K27ac) p300 in an enzymatically independent manner, while loss of KDM6A results in reduced H3K4me1 and p300 binding instability [Wang et al., 2017]. This is curious in that H3K27me1 indicates a "poised" or repressed state of activation, and this methyl group must be removed to allow for activating H3K27ac by p300 [Kouzarides et al., 2007; Fang et al., 2014]. Furthermore, activity by KMT2D at H3K4 requires activity by p300, which in turn enhances activity by p300, however this feedback cycle is initiated by KDM6A in a demethylase-independent manner, suggesting some other mechanism at play in preparing the H3K27 site [Wang et al., 2017].

Structure and Subunits

COMPASS stands for Complex of Proteins Associated with Set1, named for its original discovery in yeast, which only possesses one form of this complex [Roguev et al., 2001]. The human genome possesses six orthologs of the COMPASS family, namely SET1a, SET1b, and MLL1-4, but the MLL4 member has been the most extensively studied to date [Ruthenburg et al., 2007; Takahashi et al., 2011; Shilatifard et al., 2012; Lee et al., 2013; Sze et al., 2016; Froimchuk et al., 2017]. COMPASS/MLL4 contains five main subunits (KMT2D, KDM6A, PTIP, PA1 and NCOA6) along with four associated factors collectively referred to as the sub-complex WRAD (WDR5, RbBP5, ASH2L, and DPY30) [Takahashi et al., 2011; Shilatifard et al., 2012; Sze et al., 2016; Froimchuk et al., 2017]. PTIP and PA1 are unique to COMPASS/MLL4 and its sister

complex COMPASS/MLL3 [Froimchuk et al., 2017]. A visual representation of the estimated structure of this complex is demonstrated in Figure 3. The KMT2D protein, itself, is considered to be the main structural component, and contains an enzymatically active SET domain, which has been shown to be crucial for maintaining the stability and nominal activity of the overall complex [Ruthenburg et al., 2007; Takahashi et al., 2011].

Disease Mechanism(s)

KMT2D, indeed the COMPASS/MLL4 complex in general, has been shown to play critical roles in diverse processes like early embryonic and postembryonic development (maintenance of pluripotency and establishment of cell fate), tumor suppression and even regulation of circadian rhythms [Kim et al., 2014; Kantidakis et al., 2015; Rickels et al., 2016; Wang et al., 2016; Yan et al., 2018; Schwenty-Lara et al., 2019]. Despite numerous findings regarding the functional importance of COMPASS/MLL4 catalytic domains in selective gene expression, it is notable that a few recent studies determined COMPASS/MLL4 possessing enzymatically deficient KMT2D 1) does not result in a major loss of H3K4me1 at enhancer sites, 2) does not drastically hinder RNA synthesis at associated promoter sequences and 3) does not prevent exiting from a pluripotent state in murine embryonic stem cells [Dorighi et al., 2017; Cao et al., 2018]. This indicates that KMT2D driven monomethylation at enhancers is only a minor portion of the overall capacity by COMPASS/MLL4 to regulate gene expression and aligns with the previously mentioned finding by Wang et al., that enzymatic activity by UTX-1 is also not exclusively required to drive enhancer activation. In all of these cases, complete knockout or removal of the proteins within the complex is necessary to

significantly disrupt normal patterns of expression. Together, such findings represent a serious enigma concerning the etiology of genetic conditions like Kabuki syndrome, whereby mutations in either *kmt2d* or *kdm6a* result in significant developmental defects, but the nature of these mutations are highly variable and neither expression of KMT2D or KDM6A is totally lost [Ng et al., 2010].

C. elegans Homologs

As briefly stated in the introduction, the COMPASS/MLL family of complexes are widely conserved, with human orthologs having been identified in species ranging from single-celled eukaryotes to vertebrates [Froimchuk et al., 2017]. The original discovery of this complex was identified using a yeast model and has been extensively studied in fly as well as nematode models [Roguev et al., 2001; Ruthenburg et al., 2007; Fisher et al., 2010; Greer et al., 2010; Maures et al., 2011; Mohan et al., 2011; Rickels et al., 2016]. Members of the *C. elegans* COMPASS/MLL complex, namely SET-16 (KMT2D homolog) and UTX-1 (KDM6A homolog) have been shown to be critical in regulating developmental processes and lifespan, as well as fertility [Fisher et al., 2010; Greer et al., 2010; Vandamme et al., 2012]. However, a cardinal difference between the *C. elegans* homolog and human COMPASS/MLL4 is that loss of a single allele of SET-16 or UTX-1 has no overt phenotype, in contrast to the severe developmental phenotypes observed upon loss of a single allele of KMT2D or KDM6A in humans [Anderson and Horvitz, 2007]. This makes it impossible to study the basis of haploinsufficiency in *C. elegans*, and requires and new experimental approach.

AID/SCF-TIR1

Natural Context

The auxin inducible degron (AID) system is derived from a pathway in plants—in this case, specifically *Arabidopsis thaliana*—whereby the presence of the plant hormone auxin (IAA17: indole-3-acetic acid 17) is required for initiating target protein proteasomal degradation [Teale et al., 2006]. Degron is short-hand for 'a domain to induce degradation.' In plants, the AID system plays a key role in regulating patterns of gene expression during growth and development by acting as a conditional and selective repressor of protein products, aiding in processes like lateral root formation, orientation, and cellular elongation [Ruegger et al., 1998]. This is accomplished when a degron-tagged protein is marked for proteasomal destruction by the E3 ubiquitin ligase complex SKP1-CUL1-F-Box, or SCF (Skp1: S-phase kinase-associated protein; Cul1: Cullin-1; Rbx1: RING-box protein 1) combined with the F-box protein TIR1 (Transport Inhibitor Response 1), wherein, upon recognition of auxin, this SCF^{TIR1} complex recruits an E2 ligase resulting in polyubiquitylation of the degron, initiating proteasomal destruction of the tagged protein [Teale et al., 2006; Nishimura et al., 2009].

System Usefulness

While TIR1 orthologs have only been discovered in plants, the SCF complex—Skp1 in particular—exists, in some form, in all eukaryotes [Nishimura et al., 2009]. Because the SCF directed proteasomal pathway is so widely conserved, it has been possible to generate other organismal models that efficiently incorporate the AID-tag and

TIR1 constructs, allowing scientists to perform controlled, reversible, protein degradation studies across multiple developmental timepoints and within specified tissue types [Nishimura et al., 2009; Morawska et al., 2013; Zhang et al., 2015; Daniel et al., 2018]. What truly makes this approach unique is the level of control allotted to the user. Other methods of controlled depletion have traditionally relied on the use of genetic disruptors like CRISPR/Cas9 directed DNA mutations or RNAi, however, these methods do not target the protein products directly, and instead act at the level of transcription or translation [Fire et al., 1998; Cong et al., 2013]. Therefore, protein stability *in situ,* as well as its specific role during development, potentially become limiting factors in these types of experiments. This necessarily results in a buffering to the temporal effect of the treatment, and is frequently associated with off-target effects. With this system, though, simply adding purified auxin to the environment, or incorporating it into the food/water supply, reliably induces AID-mediated destruction of target proteins in the model organism. Removal of auxin relieves this effect (Figure 4).

Successful Applications

This degron system was first reengineered and tested in the budding yeast *Saccharomyces cerevisiae*, where researchers demonstrated that both the AID and TIR1 constructs could be inserted into the genome of a non-plant organism and could efficiently reduce endogenous Mcm4 (mini-chromosome maintenance) protein levels, resulting in impaired colony formation [Nishimura et al., 2009]. Later, in another study, also within a yeast model, researchers were able to reduce the size of the AID construct from a 229 amino acid full-length IAA17 protein to just 44 amino acids, reducing the

destabilizing effect induced by fusion of the tag to the target protein [Morawska and Ulrich, 2013]. Following this, the minimized AID construct was successfully inserted into the genome of *C. elegans*, where researchers demonstrated that auxin-inducible degradation of target proteins was efficient and reversible in an animal model [Zhang et al., 2015]. More importantly, though, Zhang *et al.,* (2015) also established generalized tissue specificity by driving TIR1 expression from either the *eft-3* promoter and *unc-54* 3' UTR for somatic tissues or the *sun-1* promoter and 3' UTR for germline tissues, effectively demonstrating controllable depletion within specific tissue types.

Recently, it was demonstrated that the AID/TIR1 system could be employed as a means of controlling reproductive timing in *C. elegans* by using the degron to target a gene that regulates spermatogenesis, *spe-44*, thus allowing researchers to control fertility [Kasimatis et al., 2018]. More work has been done in recent years to refine the specificity of this genetic tool-kit. It was understood upon the initial development of this system that off-target or auxin-independent effects could be a potential issue. Fortunately, researchers determined that co-expressing the PB1 domain of the *Arabidopsis* auxin response factor (ARF) improved the effectiveness of the AID construct, both decreasing the occurrence of auxin-independent degradation and increasing the rate at which auxin-mediated degradation takes place following exposure [Sathyan et al., 2019]. However, this finding is still relatively new and has not yet been incorporated into many other AID oriented studies.

Hypothesis and Research Aims

Controlled temporal and systematic depletion of KMT2D and KDM6A homologs by auxin induced degradation (AID) will demonstrate titratable manipulation of gene expression and identify associated elements of regulated lysine histone methylation, through visible expression and transcriptomic profile.

Experimental Goal

Here, the overarching goal was to demonstrate titratable, spatiotemporal control of gene expression using the AID/TIR1 system, with the added intent of using this system to catalog transcriptional responses to manipulating histone lysine methyltransferase and lysine demethylase activity by KMT2D and KDM6A homologs, respectively. To date, this auxin dependent system has only been employed to induce a total depletion of selected protein targets, using higher concentrations of the hormone to produce the strongest degradative effect. However, previous studies have not exploited the ability of this system to induce controlled reduction of a particular protein to an arbitrary level, as opposed to complete removal, by gauging the concentration of auxin used. Incomplete depletion would be more comparable to pathological cases of haploinsufficiency, in which not all of the protein product is lost or fails to translate, but enough depletion has occurred to generate an aberrant phenotype. As previously mentioned, Kabuki syndrome is caused by haploinsufficiency of either KMT2D or KDM6A. This experiment is intended to model that pathological state in an organism that can be easily monitored and analyzed through each stage of development.

Specific Aim 1

Hypothesis—The AID system, paired with expression of TIR1, can be used to conditionally knock-down KMT2D and KDM6A to arbitrary levels.

While knock-out models have been historically useful for establishing a firm understanding of broad mechanisms across species, many of the more subtle mechanisms involved in a majority of developmental disorders and chronic illnesses cannot be readily addressed through a simple knock-out. Instead, having the ability to conditionally—reversibly—alter product concentration *in vivo* would be far more appropriate. Here, such a model will be demonstrated using four genetic strains of *C. elegans* engineered to co-express AID-tagged SET-16, along with expression of TIR1 either from a somatic or germ-line promoter, as previously described. AID will be expressed from the same promoter of SET-16 along with GFP for visual confirmation of expression—TIR1 is tagged with mRuby and is coexpressed from either the *eft-3* promoter for somatic tissues, or the *sun-1* promoter for germline tissues. Results demonstrate the effective removal of SET-16 from oocyte nuclei in young adults when auxin is present, conditional upon co-expression of TIR1 (data not shown), and that knock-down is reversible upon auxin removal. This experiment is intended to demonstrate a titratable response to auxin and will allow for analysis of phenotypic changes at particular expressive thresholds.

Specific Aim 2

Hypothesis: Transcriptomic analysis of whole organisms at various auxin concentrations will reveal changes to overall expression patterns, identifying developmental targets of KMT2D and KDM6A activity.

Given the expectation that the COMPASS/MLL complex is highly regulated throughout development, interrupted activity by auxin induced degradation is likely to result in detectable changes in the expression of tissue-specific target genes. Whole exome RNA sequencing is a useful method for identifying changes in gene expression. RNA analysis of the entire transcriptome in each hybrid strain, under conditions of varying auxin concentration, and thus, variable KMT2D or KDM6A depletion, will provide a detailed profile of the transcriptional changes that result from a reduction in histone H3K4 mono-, di-, and tri-methylation, as well as from reductions in H3K27 demethylation. These findings are intended to demonstrate the viability of candidate genes as therapeutic targets in treating lysine methyltransferase specific developmental disorders, such as Kabuki syndrome. Importantly, because Kabuki syndrome arises from *de novo* mutations during embryonic development and not familial inheritance, somatic tissues will be targeted for transcriptomic analysis, in an attempt to disentangle the effects of maternal and zygotic altered histone methylation activity.

Chapter II.

Materials and Methods

All experiments were performed in triplicate. Each replicate consisted of freshly made medium and independent synchronized populations of animals. For routine strain maintenance, populations were stored at 20˚C, cultured on standard NGM plates and passaged twice per week to prevent overcrowding or starvation, according to standard protocols [Brenner et al., 1979].

Auxin Preparation

Auxin plates were prepared from a 400mM liquid stock made of auxin, (Indole-3-acetic acid, IAA) (MW=175.19) dissolved in ethanol, prepared fresh monthly. Auxin stocks were stored at 4˚C in the dark and were replaced after 30 days. Auxin plates were prepared using four concentrations: 1.0mM, 0.1mM, 0.01mM, and 0mM (control). To account for additional solvent, all volumes were made to contain a final concentration of 0.25% ethanol. Plates were stored under the same conditions as the 400mM auxin stocks, at 4˚C away from light and were not kept beyond 30 days. Plates were prepared 4-5 days prior to the start of each experiment and new plates freshly prepared for each experimental replication. Any plates showing signs of contamination or chemical breakdown (yellowing of agar, presumably due to auxin decomposition) were not used for experiments. Plates were seeded with laboratory strain *Escherichia coli*, OP50, 2-3 days prior to plate use, allowing for sufficient growth of a feeder lawn. For higher

concentrations of auxin, it was sometimes necessary to first concentrate OP50 stock by centrifugation to yield a higher density for seeding [Zhang et al., 2015].

Population Preparation

All animals used for experiments were synchronized first larval stage (L1) progeny prepared by bleach treatment of gravid adults. Synchronization was accomplished by washing animals into Eppendorf tubes using M9 medium, followed by brief centrifugation and removal of excess solution. Bleaching solution was prepared by mixing sodium hydroxide, sodium hypochlorite, and water in a 1:1:2 ratio. Washed animals were suspended in 2mL bleaching solution for ~4 minutes, with occasional mixing by hand shaking. Once all adults were lysed, remaining embryos were washed up to 5 times in M9 to remove residual bleach from the sample, and suspended in clean M9 medium. Samples were then placed on a rotator overnight. The following morning, hatched L1s were deposited onto standard, seeded NGM plates and allowed to reach the L4 stage before transfer to an auxin containing environment. Their progeny were then selected at either the L4 stage or as day 1 adults, depending on the intended procedure.

Fluorescence Imaging of Germline GFP

Specimens for imaging were mounted onto 2% agarose gel pads and anesthetized using 30uL 100mM sodium azide. Images were acquired using a Deltavision Core imaging system (Applied Precision) with UApo/340 40×1.35NA, PlanApo 60×1.42NA and U- PlanApo 100×1.4NA objectives (Olympus) and a CoolSnap HQ2 camera with settings at 100% transmittance for GFP fluorescence (EX) with 300 msec exposure time. Brightfield (polarized (POL)) images were collected with the exposure time adjusted to 25 msec to compensate for brightness saturation of images. All images were acquired using the 60X objective. Images were taken of L4 stage animals, or 1-day adults with grossly normal appearance and at least four pre-fertilization oocytes with readily discerned nuclei. Brightness differences were calculated using both germline hybrid strains for SET-16, *ieSi64* II; *set-16*(*syb1046*)III, and UTX-1, *ieSi64* II; *utx-1*(*syb1026*)X. See Table 1 for a full list of strains and brief descriptions. All images were processed using Fiji Imaging Software. For each nuclei, three measurements were taken: one of the nucleus center, one of the ventral oocyte cell body, and one of the dorsal oocyte cell body. The average background intensity value was calculated from the two measurements derived from the cell body, and this value was subtracted from the center nucleus measurement. The final calculated value was considered to be the intensity of nuclear GFP expression in germline cells.

Fluorescence imaging of Somatic GFP

Samples were imaged using the same methodology described above. All images were acquired using the 40X objective. Images were taken at the L1 and L2 stages. Brightness differences were calculated using both somatic hybrid strains for SET-16, *ieSi*57 II; *set-16*(syb1046)III, and UTX-1, *ieSi*57 II; utx-1(syb1026)X. See Table 1 for full list of strains and brief descriptions. All images were processed using Fiji Imaging Software. For each animal imaged a total of five measurements were taken of tail nuclei followed by a single measurement from tail background. This background measurement was then subtracted from each nuclear measurement. The final calculated values were considered to be the actual difference in intensity of nuclear GFP expression in the soma.

RNA Purification

For RNA purification, animals from each strain were washed from seeded agar plates using standard M9 buffer solution into 1mL Eppendorf tubes and centrifuged to form a pellet. M9 supernatant was removed and the pellet was washed 2-3 times with clean M9 to remove bacterial contamination. Animals were left suspended in M9 and placed on the rotator for ~30-60 min in order to allow for clearance of the gut. The animals were then washed once more before final removal of the supernatant. Next, around 150-250µL Trizol was added depending on the overall volume of animals recovered, with an estimated ratio of 2:1 Trizol to pellet volume. The solution was then vortexed for 1 minute and submerged in liquid nitrogen until frozen, followed immediately by a water bath at 40˚C. Once thawed, the sample immersed again in a liquid nitrogen bath and this process was repeated at least 5 times to ensure complete rupture of the cuticle and RNA exposure to Trizol. Next, dependent on sample volume, 50-100uL chloroform was added, vortexed for ~30 sec, and centrifuged at 12,000 rpm for 15 min at 4˚C. The upper aqueous layer was transferred to an RNase free Eppendorf tube, and centrifuged once more using the above conditions. The aqueous layer was then transferred to another RNase free eppendorf tube and this process was repeated 2-3 more times, as needed. Next, 125uL 2-propanol was added and mixed gently, without vortexing, followed by centrifugation at 12,000 rpm for 10 min at 4˚C. The supernatant was then removed and discarded and the remaining pellet washed with 250-500uL 70% ethanol (RNase free). The solution was centrifuged at 14,000rpm for 5 min at 4˚C. Ethanol was completely removed and the pellet allowed to dry before dissolving in ~10-25uL RNase free water, again dependent on recovered pellet size.

DNA contamination was removed using an Invitrogen TURBO DNA-*free* Kit (ThermoFisher Scientific) according to User Guide instructions: ~33uL RNase free water was added to an RNase free eppendorf tube, followed by 10ug RNA sample (calculated from the total estimated yield, determined via NanoDrop ND-1000 spectrometer) with the addition of 5uL 10X TURBO DNase Buffer with 1uL TURBO DNase Enzyme. The solution was then mixed gently, without vortexing and incubated at room temperature for 20-30 min. Finally, 1uL of 0.5M EDTA was added to neutralize DNase enzymes and the solution was incubated at 65˚C for ~10 min. The sample was then placed on dry ice and delivered to the Dana-Farber Cancer Institute Molecular Biology Core Facility for sequencing.

Bioinformatics

RNA sequencing was performed on a total set of 24 samples representing somatic depletion of SET-16 and UTX-1 under four auxin concentrations (0mM, 0.01mM, 0.1mM, and 1mM) in three full replicates. RNA sequencing was also performed on a single replicate of eight samples representing germline depletion of SET-16 and UTX-1 under the same four auxin conditions mentioned above.

The resulting fastq files containing the RNA sequencing reads were processed in collaboration with Dr. Jaejoon Choi and Dr. Alice Lee (Roya Kabuki Program at Boston Children's Hospital) using the following analytical pipeline: 1) reads were aligned to the c_elegans.PRJNA13758.WS274 genome (wormbase.org) and HTSeg was used to count the number of aligned reads per gene. 2) DESeq2 was used to determine a list of differentially expressed genes (DEGs) that resulted from developmental exposure to each

auxin condition. 3) A functional enrichment test (https://wormbase.org/tools/enrichment/tea/tea.cgi) was performed on each DEG list to establish which biological functions are related to expression patterns that are altered.

A list of all DEGs that were commonly identified upon somatic depletion of both SET-16 and UTX-1, showing Log2FoldChange and adjusted p-values, can be found in the Supplemental Table Data section (Table S1). No table for germline depletion has been included as only one DEG was identified.

Chapter III.

Results and Interpretation

Oocyte Nuclear GFP Intensity

To determine if intermediate levels of protein depletion can be achieved by titrating auxin concentrations, animals expressing SET-16-AID-GFP or UTX-1-AID-GFP with TIR1 expressed in the germline or soma were cultured on 0mM, 0.01mM, 0.1mM, or 1 mM auxin and the resulting GFP intensity in the germline (pre-fertilization oocytes) or soma (a group of cells in the tail) was measured. Upon calculating nuclear GFP intensity values, a trend in the data was visible for both the germline and somatic depletion strains (Figures 5.1-8.2).

SET-16 germline and soma depletion strains produced linear downward curves in response to increasing auxin concentration, with the highest concentration (1.0mM) yielding the greatest reduction in GFP intensity. For SET-16 germline depletion, the average value of nuclear GFP intensity in the absence of auxin was 201.72±78.62; at 0.01mM, 135.06±88.35; at 0.1mM, 78.39±74.26; and at 1.0mM, -0.187±51.01 compared to background. For SET-16 somatic depletion, the average value of nuclear GFP intensity without auxin was 356.74±129.45; at 0.01mM, 265.37±134.94; at 0.1mM, 86.45±97.21; and at 1.0mM, 4.13±29.66 compared to background.

UTX-1 strains demonstrated a steeper response curve to auxin with GFP intensity being abolished at 0.1mM concentration. The average nuclear GFP intensity value without auxin for UTX-1 germline depletion was 172.6±58.96; at 0.01mM, 34.86±58.96; and at both 0.1mM and 1.0mM, the adjusted intensity value fell below 0 (-28.62±30.55

and -23.69±21.21, respectively) due to higher background autofluorescence in cytoplasm. For UTX-1 somatic depletion the average value of nuclear GFP intensity in the absence of auxin was 361.24±118.30; at 0.01mM, 52.19±54.52; and at both 0.1mM and 1.0mM the signal was essentially absent (10.80±21.38 and -4.23±19.21, respectively).

While SET-16 is the major component of the *C. elegans* COMPASS/MLL complex, UTX-1 appears to show a higher sensitivity to auxin induced depletion (Figures 7.2 & 8.2). This is possibly related to it being a more peripheral component of the complex and thus more accessible to the degradation machinery. However, loss of SET-16 results in a stronger phenotypic response and greater reduction in overall brood-size (Figures 9.1-10.2). These data show that the auxin degron system can be used to deplete a protein of interest to arbitrary levels, in order to study dosage-sensitive effects. Importantly, these results also show that the dose-response curve for depletion needs to be empirically evaluated for each protein under study, as different proteins—even members of the same complex—can exhibit strikingly different response curves.

Transcriptomic Analysis

To determine how partial depletion of SET-16 and UTX-1 affect phenotype, in this case gene expression, transcriptomic analysis was performed on the somatic depletion strains at each auxin concentration. Statistical analysis of RNA-seq data from whole animals identified altered expression of 4047 genes following somatic depletion of SET-16 (1969 upregulated; 2078 downregulated) and 569 genes following somatic depletion of UTX-1 (432 upregulated; 137 downregulated). Among these data sets there were 390 genes with altered expression in both strains that follow approximately the

same trends in response to auxin exposure (Figure 11; Table S1). From that list, there are several candidates that stand out as being the most statistically significant and with the greatest fold change: for example, the uncharacterized gene *Y70C5A.3* had the greatest reduction, showing a -1.9-fold and -2.2-fold decrease in gene expression after SET-16 and UTX-1 depletion, respectively, with an adjusted p-value ≤ 0.00001 in either case. It should also be noted that from transcriptomic analysis of germline strains only a single DEG was identified, *his-63*, with an adjusted p-value of ≤ 0.05 in either case. It is interesting to note this gene was downregulated by both depletion of SET-16 and UTX-1 but was not identified in the somatic depletion data set.

These data contain a few features that are worth addressing further:

1. A greater number of DEGs for both depletions are up-regulated, suggesting that the overall effect of the wild-type COMPASS/MLL complex is to indirectly reduce gene expression during development. This is surprising in that KMT2D and KDM6A promote transcription (through H3K4me and H3K27me, respectively) so their depletion would be expected to result in wide-spread down-regulation, however this was not observed.

2. Some genes demonstrate a steeper response curve to auxin induced depletion, suggesting that the COMPASS/MLL complex must also rely on activity by other transcription regulating factors for the majority of its targets, but that some genes are more dependent on the specific patterns of histone methylation deposited by this complex, possibly highlighting suitable genetic candidates as therapeutic targets. This might demonstrate why Kabuki syndrome can present with so many degrees of severity in patient cohorts, but all cases still maintain those previously described

cardinal features used to identify the condition in a clinical setting, which would indicate a set of genes whose expression is consistently affected by this disease.

3. Gene-set enrichment tests showed that a significant number of down-regulated genes after somatic depletion of SET-16 promote male-like phenotypes, germline development and reproductive system growth (Figure 12.2). Notably, reduced fertility was observed for this strain, noticeable in both the number of oocytes present in mature adults as well as in overall fecundity (Figures 6.1 & 9.1). In both SET-16 and UTX-1 somatic depletions, gene-sets for sensory neurons including the outer labial sensilla, and PVD neurons were up-regulated. This is interesting as neurological disorders are frequently reported in human Kabuki patients.

4. Many of the commonly identified DEGs are members of the same family of genes (for example, 24 out of a total of 39 members from the "*pals*-," or Protein Containing ALS2cr12 Signature family; Figure 14), which are present in the genome as a large gene cluster. This result suggests that the COMPASS/MLL complex possibly regulates gene expression across a chromosomal locus i.e. this complex governs multiple genes on the basis of their physical position in the genome.

5. Lastly, because 390 DEGs were identified by analysis after somatic depletions but only one DEG after germline depletion, this may suggest that the larger number of affected genes seen in somatic depletion suggests a major role for UTX-1 and SET-16 in the ongoing maintenance of gene expression, while the smaller number of affected genes seen in germline depletion suggests that normal expression of these factors within the zygote is sufficient for healthy development.

Chapter IV.

Discussion

Firstly, Specific Aim 1 of this project determined via quantification of GFP intensity that the AID/TIR1 system can induce titrated depletion of a specific gene product at the protein level. Importantly, the extent of protein depletion is directly determined by the concentration of auxin used. This is advantageous in that it allows for arbitrary reduction of *in situ* protein levels that can be readily reversed by simply removing auxin from the environment. Previous methods for producing knockout models focus on eliminating protein expression, yet many human diseases arise from dose-dependent effects that may differ markedly from complete loss of function. Second, transcriptomic analysis using RNA-seq has identified 390 genes (329 upregulated, 61 downregulated) whose expression is altered by both the loss of KMT2D (Kabuki syndrome type 1) and KDM6A (Kabuki syndrome type 2) homologs, potentially establishing candidates that are responsible for the related symptoms between both types of syndrome. Gene-sets responsible for governing the development of the reproductive and neurological systems as well as sex specific phenotypes were mainly affected by these depletion experiments (Figures 12.1-13.2). Whether this is connected to developmental defects in human cases of Kabuki syndrome is yet to be determined, however this data suggests that there is a significant correlation between insufficient expression of KMT2D (SET-16) or KDM6A (UTX-1) and subsequent dysregulation of expression for many members of the same families of genes and gene-sets related to specific roles in development.

Significance

While the AID system has been employed with success in various experimental models, prior to this series of experiments the system has not been used to evaluate intermediate degrees of depletion representative of genetic disorders characterized by the haploinsufficient expression of a protein product. Previous experiments have modeled haploinsufficiency by inactivating a single allele, however there are two issues with this approach. First, unless tissue specific methods are employed, this typically results in the los of the genetic product from the very beginning of development, and does not model a *de novo* mutation that occurs during development. Second, and more importantly, traditional knockout methods are generally limited to producing 50% gene dosage. This may not be the case in patient cohorts, where hypomorphic mutations or genetic compensation may lead to other gene dosages. Further, the threshold concentration to elicit a phenotype may differ between humans and the model organism being used. Therefore, the use of an inducible degradation system is powerful simply because the extent of depletion is readily controlled by the concentration of the induction agent, in this case auxin, and thus any arbitrary gene dosage can be 'dialed-in.'

Here, the effectiveness of the AID system is demonstrated in *C. elegans* by modeling variable depletion of either SET-16 or UTX-1 reminiscent of the genetic disorder Kabuki syndrome, with the added potential for uncovering critical developmental windows in which such a loss can result in differential severity of the condition.

Future Directions

While GFP intensity calculations demonstrated a significant response to auxin inducible degradation and RNA-seq analysis shows a wide genomic response to loss of SET-16 and a mild genomic response to loss of UTX-1, phenotypic analysis and fertility measurements are still incomplete. At a glance, it is clear that higher concentrations of auxin exposure for both the SET-16 somatic depletion and UTX-1 germline depletion strains result in noticeable phenotypic anomalies within either population as well as reduced population density compared to controls (Figures 9.1-10.2). Based on the transcriptomic data, it will be useful to conduct histone immunostaining and western blot experiments to identify the relative changes to patterns of mono-, di-, and trimethylation that result from titrated depletion of SET-16 and UTX-1, as well as to identify where and when these changes are occurring during early development. Adding to this, candidate genes identified through the RNA-seq experiments can then be used to weigh the significance of these changes to normal histone H3 methylation patterns. This will potentially identify therapeutic targets that can be manually up-regulated, down-regulated or supplemented in order to compensate for haploinsufficient expression of the proper COMPASS/MLL4 complex.

Limitations

It is worth noting that previous studies that employed the AID system reported a minor degree of proteasomal degradation induced by the AID-tag in the absence of auxin [Morawska et al., 2013]. While this is not expected to have had an impact on experimental outcomes it is worth keeping in mind that some variability in phenotypic

severity across conditions will be present, even in control groups cultured on standard agar plates. Indeed, morphological defects were occasionally observed even in the absence of auxin, indicating that the tagged proteins may not be fully functional, or that the degron does sometimes initiate auxin-independent proteasomal degradation.

With regard to GFP fluorescence intensity measurements: a substantial amount of variability was observed in the overall brightness of nuclear expression in untreated animals, as well as following auxin exposure. While overall trends in the datasets are visibly and statistically present, it should be noted that measurements taken from the somatic lines demonstrate a greater degree of variability, largely due to difficulty in identifying nuclei that have reduced GFP signal, in combination with a poorer quality appearance of animals at higher auxin concentrations. In such cases, cellular backgrounds tend to appear hazier than control counterparts, returning low but non-zero values, despite no GFP signal being noticeably present in tail nuclei. Adding to this, sodium azide used to anesthetize animals tends to induce vacuoles within tissues after a short period of time, affecting fluorescence.

Conclusions

The purpose of this series of experiments was to demonstrate the effectiveness of the AID system to induce titratable depletion of a protein product to an arbitrarily defined functional level, reminiscent of a disease state caused by haploinsufficiency. This new genetic approach was successful in reducing both SET-16 and UTX-1 proteins in both somatic and germline tissues and the extent of this depletion was directly dependent on the concentration of environmental auxin that animals were raised on. In response to this

depletion, RNA sequencing results show changes, either by up-regulation or down-regulation, of associated genes that correlate with the overall extent of auxin-induced depletion of both SET-16 and UTX-1. Through verification of application of the AID toolkit, it is now possible to model a plethora of genetic illnesses, such as Kabuki syndrome, in particular, that are caused by reduced gene dosage rather than a complete null. Lastly, these series of experiments have demonstrated the critical importance of the COMPASS/MLL family of complexes in development, as even subtle depletion of SET-16 or UTX-1, using 0.01mM auxin, resulted in genome-wide changes in gene expression within the *C. elegans* model, despite animals appearing grossly wild-type. Given the importance of choreographed histone methylation during development among all organisms, diseases that result from impaired function of complexes such as COMPASS/MLL4 should be given more attention in future studies as the individuals who possess these diseases, namely Kabuki syndromes Type I and Type II, face a lifetime of health disparities with few available means of treatment.

Appendix 1.

Table 1. *C. elegans* strains used in study.

Strain Name	**Transgene**	**Description**
CA1352 “GermTIR1”	*ieSi64* II	This strain carries the TIR1 F-box protein expressing in germline tissues.
CA1200 “SomaTIR1”	*ieSi57* II	This strain carries the TIR1 F-box protein expressing in somatic tissues.
CHB3561 “SET-16”	*set-16(syb1046)* III	This strain carries the AID-GFP tagged SET-16 at its endogenous locus.
CHB3564 “UTX-1”	*utx-1(syb1026)* X	This strain carries the AID-GFP tagged UTX-1 at its endogenous locus.
SET-16/GermTIR1	*ieSi64* II; *set-16(syb1046)* III	Strain used for germline depletion of SET-16.
UTX-1/GermTIR1	*ieSi64* II; *utx-1(syb1026)* X	Strain used for germline depletion of UTX-1.
SET-16/SomaTIR1	*ieSi57* II; *set-16(syb1046)* III	Strain used for somatic depletion of SET-16.
UTX-1/SomaTIR1	*ieSi57* II; *utx-1(syb1026)* X	Strain used for the somatic depletion of UTX-1.

Appendix 2.

Figure 1. Kabuki Syndrome Patient Appearance from Front and Side.

Images depicted demonstrate each patient exhibits physiognomies consistent with the cardinal features associated with this genetic condition: eversion of the lateral lower eyelid, elongated palpebral fissures, arched eyebrows and a depressed nasal tip (Patient images by Nikawa et al., 1981).

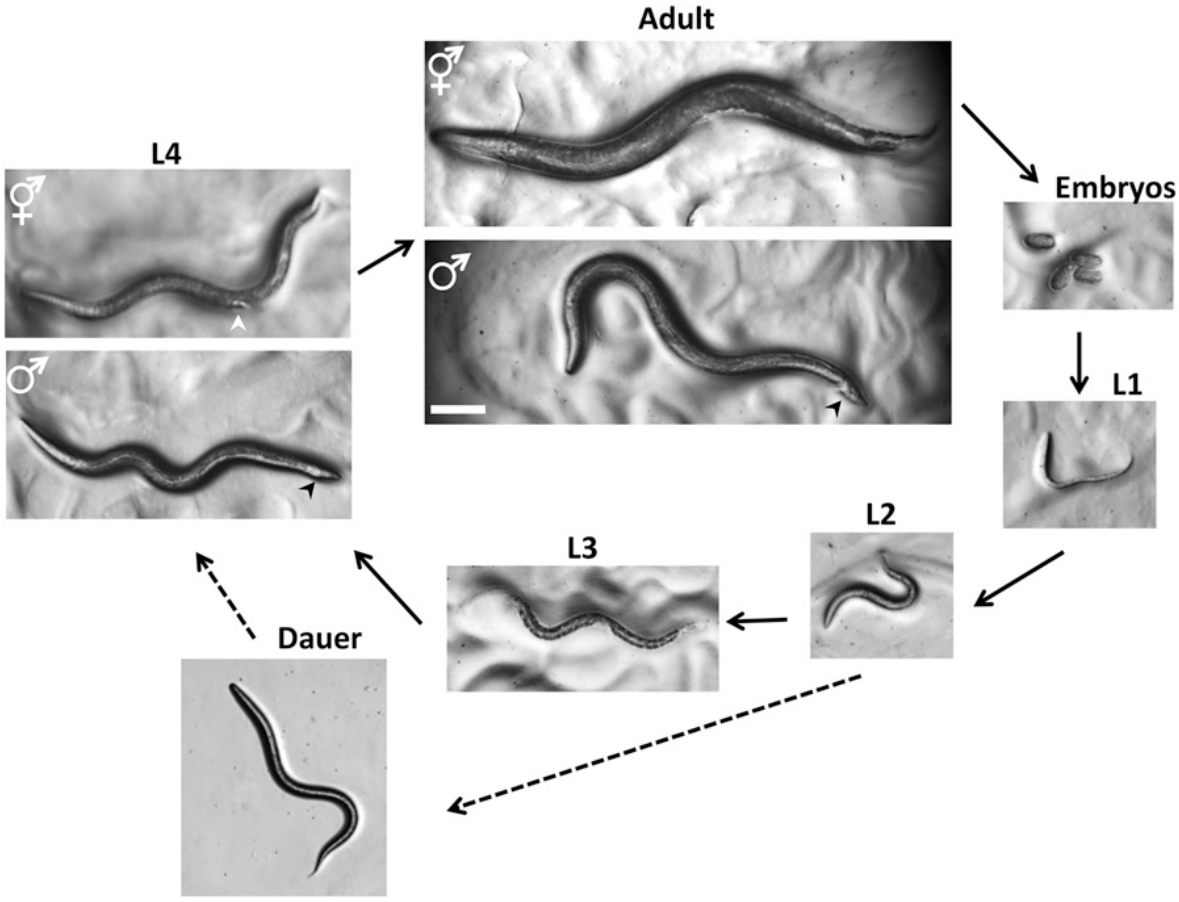

Figure 2. *C. elegans* Life-cycle and Growth Stages.

C. elegans experience six growth stages starting from fertilized embryos, then larval stages L1-L4, and into mature adults. Upon environmental stress or famine L2 larvae can enter into the dauer state, a form of active developmental hibernation, allowing them to survive harsh conditions and without food. The L4 larval stage is distinguishable by the developing vulva in hermaphrodites (white arrow). Males arise less frequently than hermaphrodites and can be distinguished through their smaller size and fanned tail (black arrow). The average life-cycle from embryo to fertile adult is 3 days at 25˚C (Figure by Corsi et al., 2015).

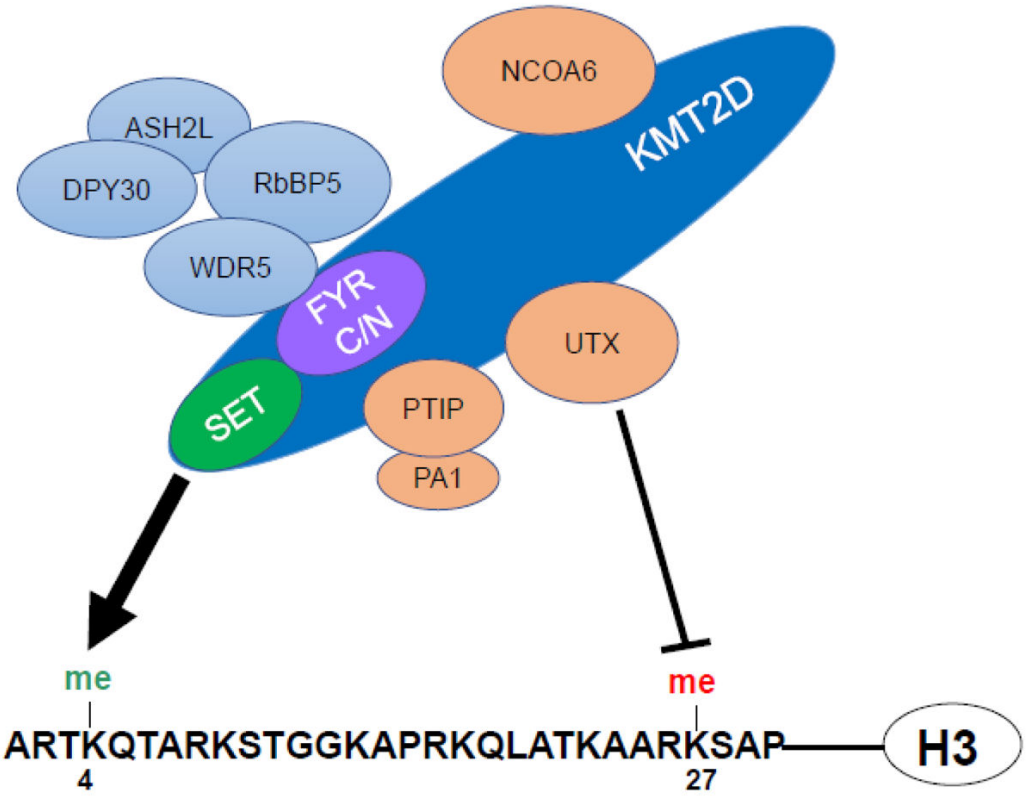

Figure 3. COMPASS/MLL4 Complex and Interaction with H3 Amino Acid Tail.

COMPASS/MLL4 complex (KMT2D, PTIP, PA1, NCOA6 and KDM6A—shown as UTX) associates with WRAD (WDR5, RbBP5, ASH2L and DPY30). Enzymatic activity by the SET domain of KMT2D methylates the fourth lysine (H3K4), associated with gene activation. Methylated H3K27 is associated with gene silencing, and is removed by KDM6A demethylase activity (Figure by Froimchuk et al., 2017).

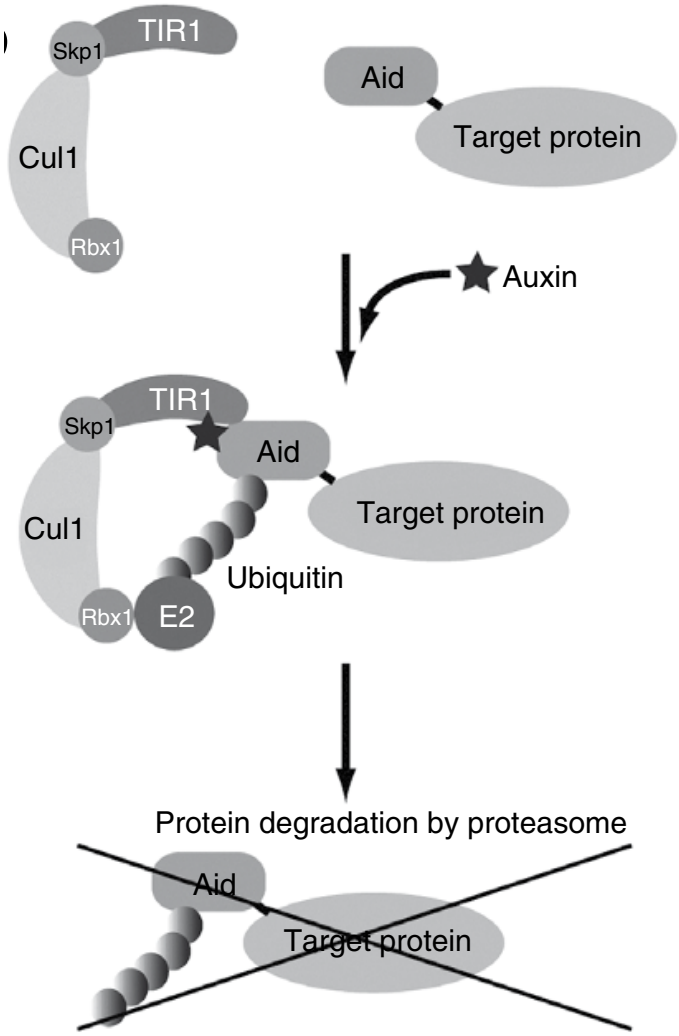

Figure 4. AID/TIR1 System Mode of Action.

Treatment with auxin (IAA: indole-3-acetic acid, represented by star) promotes binding of the E3 ubiquitin ligase SCF-TIR1 (Skp1, Cul1, Rbx1 plus TIR1) to an AID-tagged protein target leading to the recruitment of an E2 ubiquitin ligase to induce proteasomal degradation of the tagged protein (Figure by Nishimura et al., 2009).

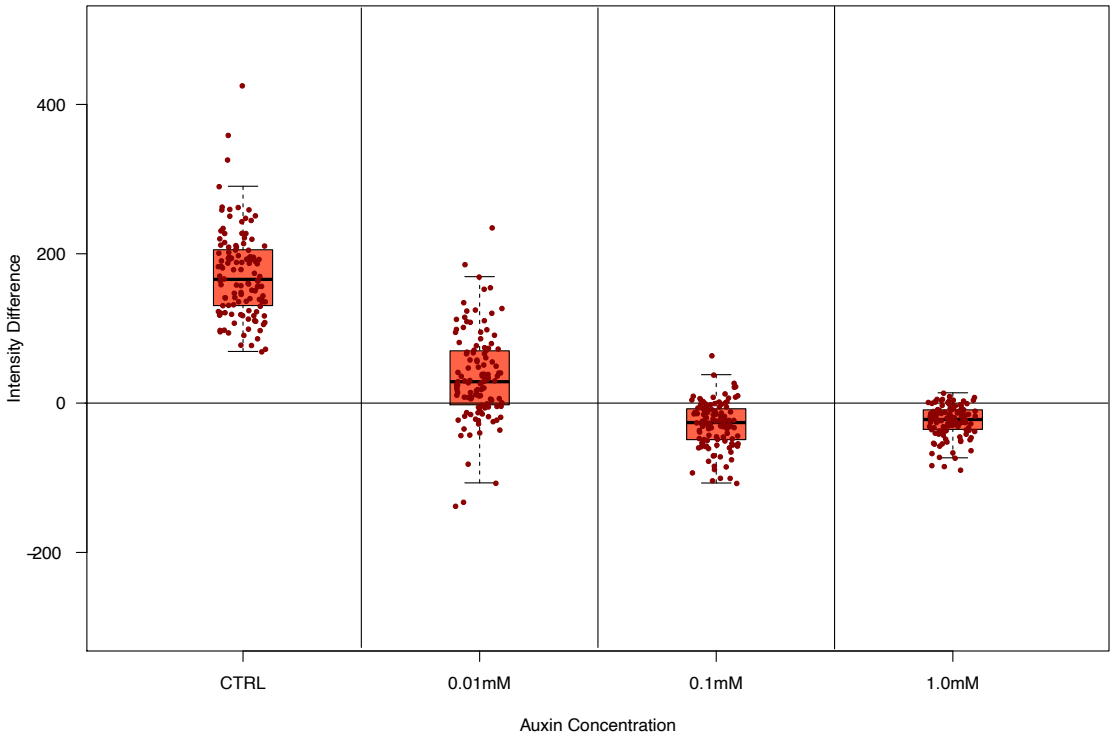

Figure 7.2 UTX-1 Germline Depletion Across a Range of Auxin Concentrations.

GFP fluorescence intensity across auxin concentrations of ieSi64 II; utx-1(syb1026) X oocyte nuclei (n=120 per condition). Individual replicates shown at right (n=40 per condition). Data points indicate mean pixel intensity calculated by the difference in nuclear GFP from background. 0.01mM auxin vs. control: p-value = $<2.2x10^{-16}$. 0.1mM auxin vs. 0.01mM auxin: p-value = $<2.2 x10^{-16}$. 1.0mM Auxin vs. 0.1mM auxin: p-value = 0.1918. P-values calculated using Wilcoxon Rank-Sum Test. (RStudio v1.2.5001)

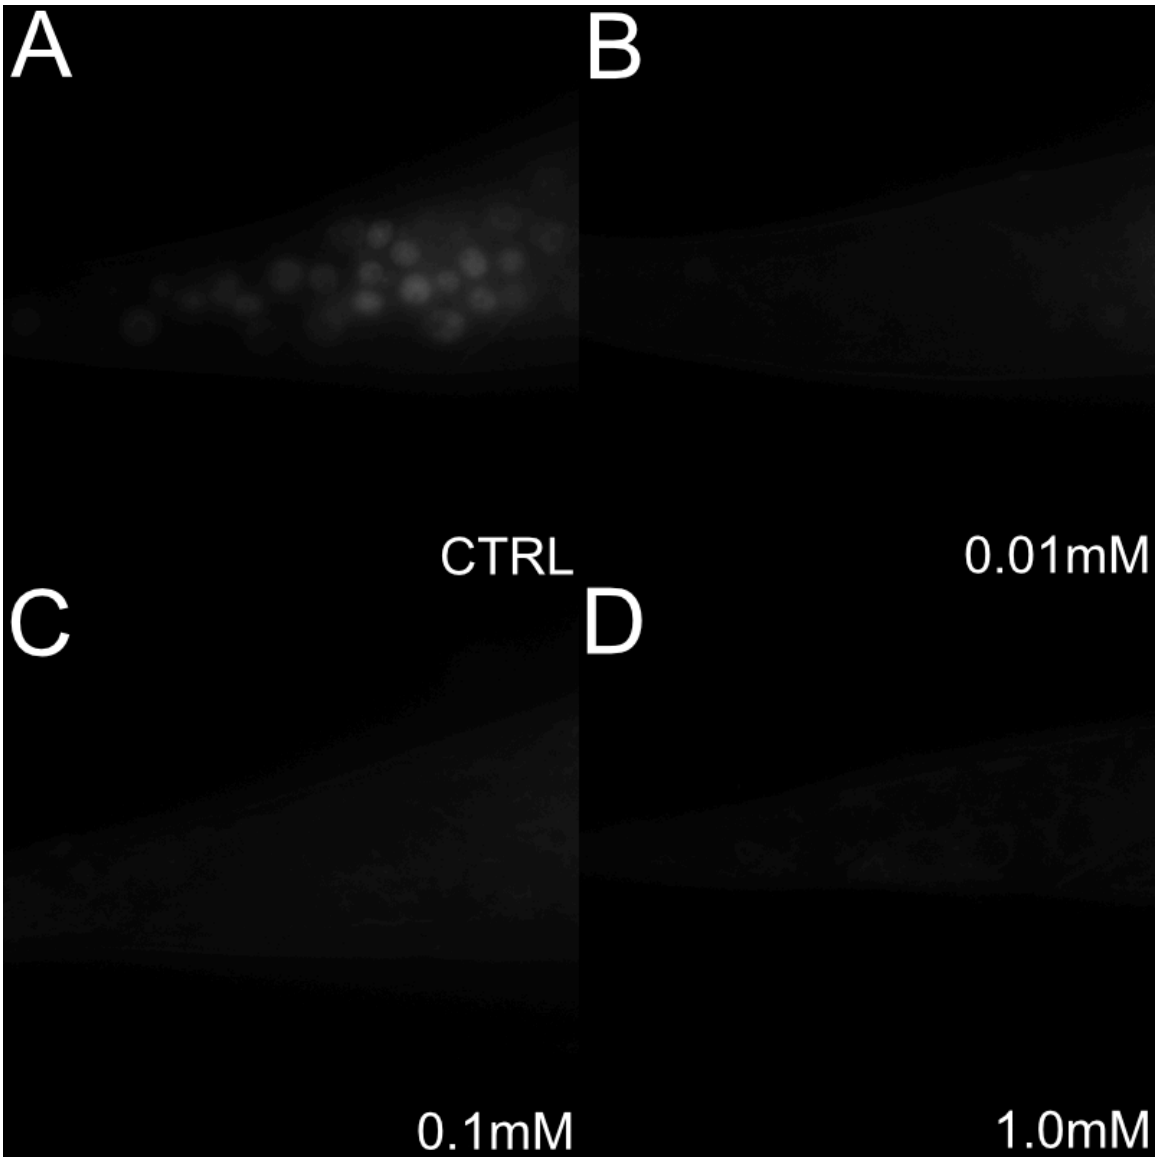

Figure 8.1 UTX-1 Somatic Depletion Across a Range of Auxin Concentrations.

Somatic nuclear GFP expression in tails of L3 stage larvae raised under four conditions: A) no auxin (control, CTRL). B) 0.01mM auxin. C) 0.1mM auxin. D) 1.0mM auxin. Images taken using DeltaVision Core imaging system at 40X magnification.

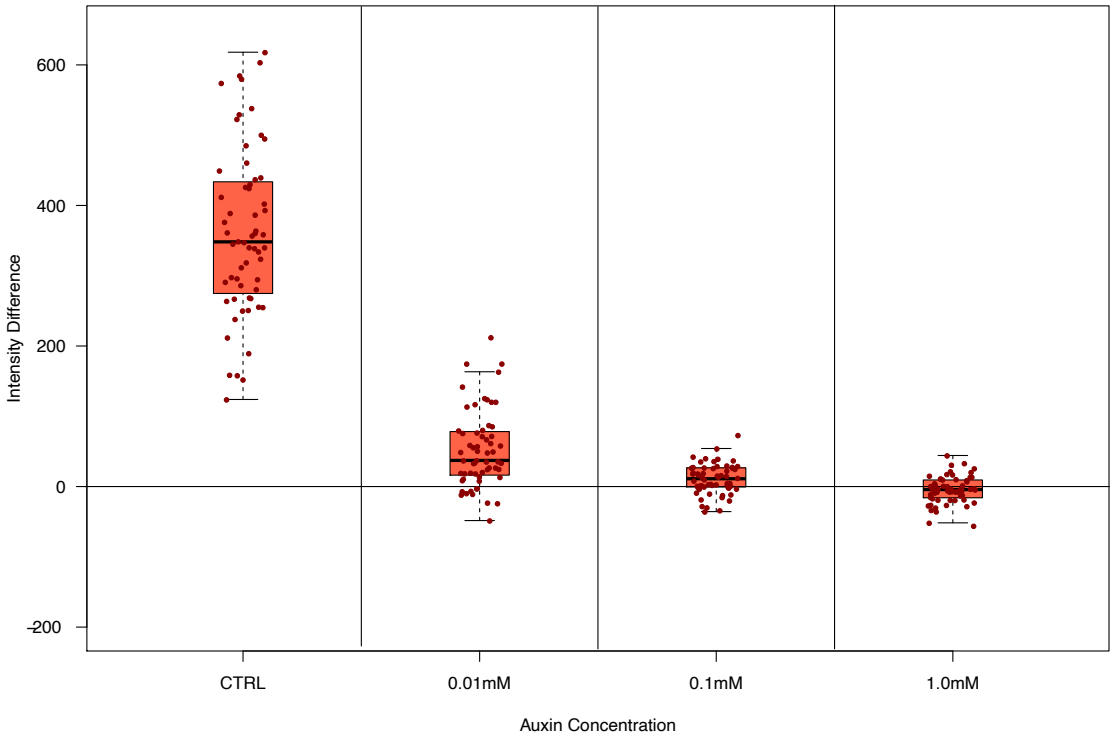

Figure 8.2 UTX-1 Somatic Depletion Across a Range of Auxin Conditions.

GFP fluorescence intensity across auxin concentrations of ieSi57 II; utx-1(syb1026) X somatic nuclei (n=60 per condition). Individual replicates shown at right (n=20 per condition). Data points indicate mean pixel intensity calculated by the difference in nuclear GFP from background. 0.01mM auxin vs. control: p-value = $<2.2x10^{-16}$. 0.1mM auxin vs. 0.01mM auxin: p-value = $<2.008\ x10^{-6}$. 1.0mM auxin vs. 0.1mM auxin: p-value = $6.006x10^{-5}$. P-values calculated using Wilcoxon Rank-Sum Test. (RStudio v1.2.5001)

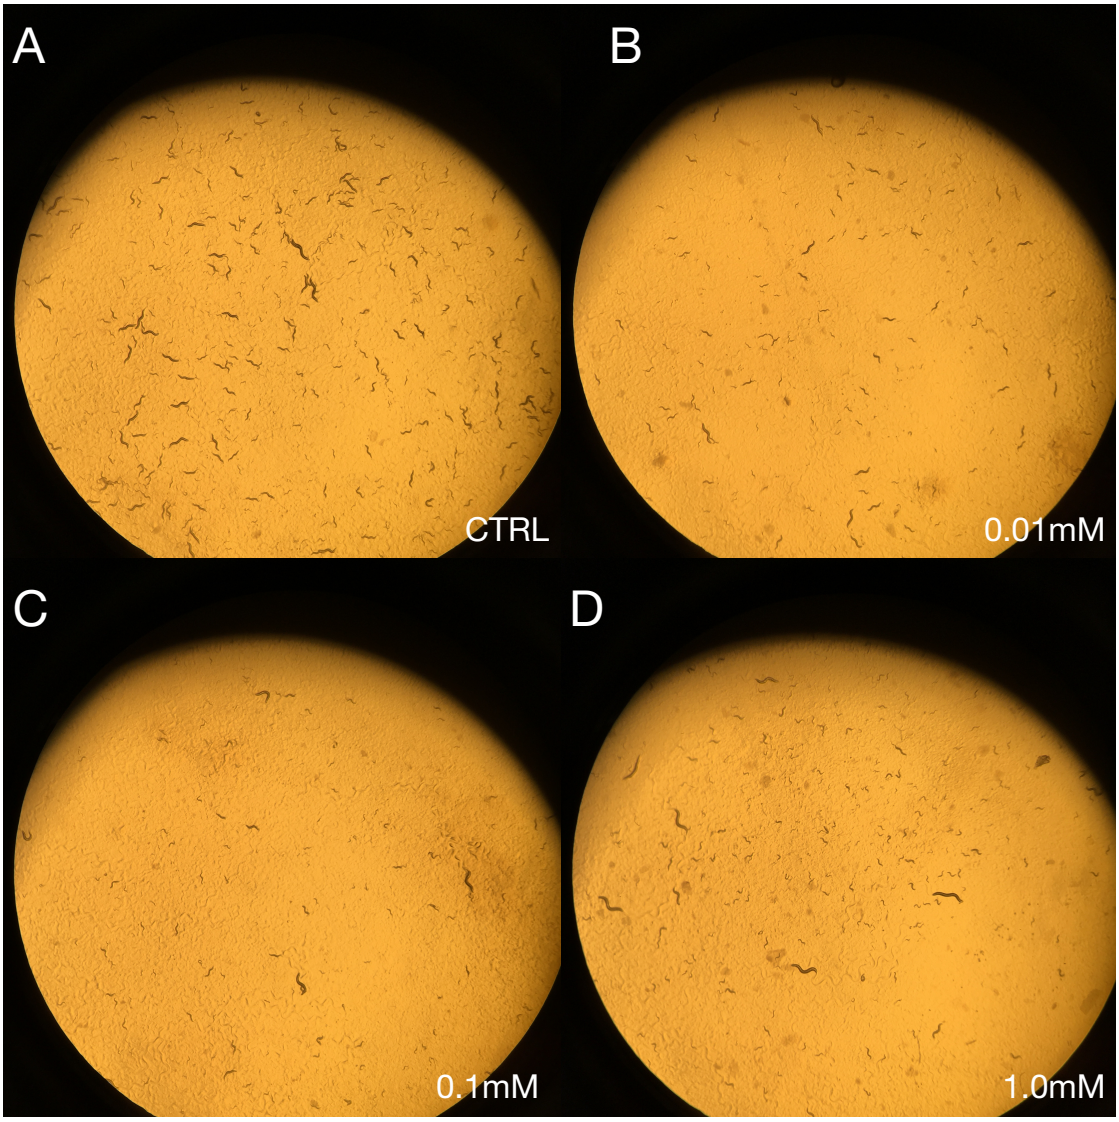

Figure 9.1 Colony Formation After SET-16 Somatic Depletion.

Somatic Depletion of SET-16 has a drastic effect on population growth at higher concentrations of auxin. Images were taken using a dissection microscope 5 days after seeding each plate with an initial 10 animals at the L4 stage.

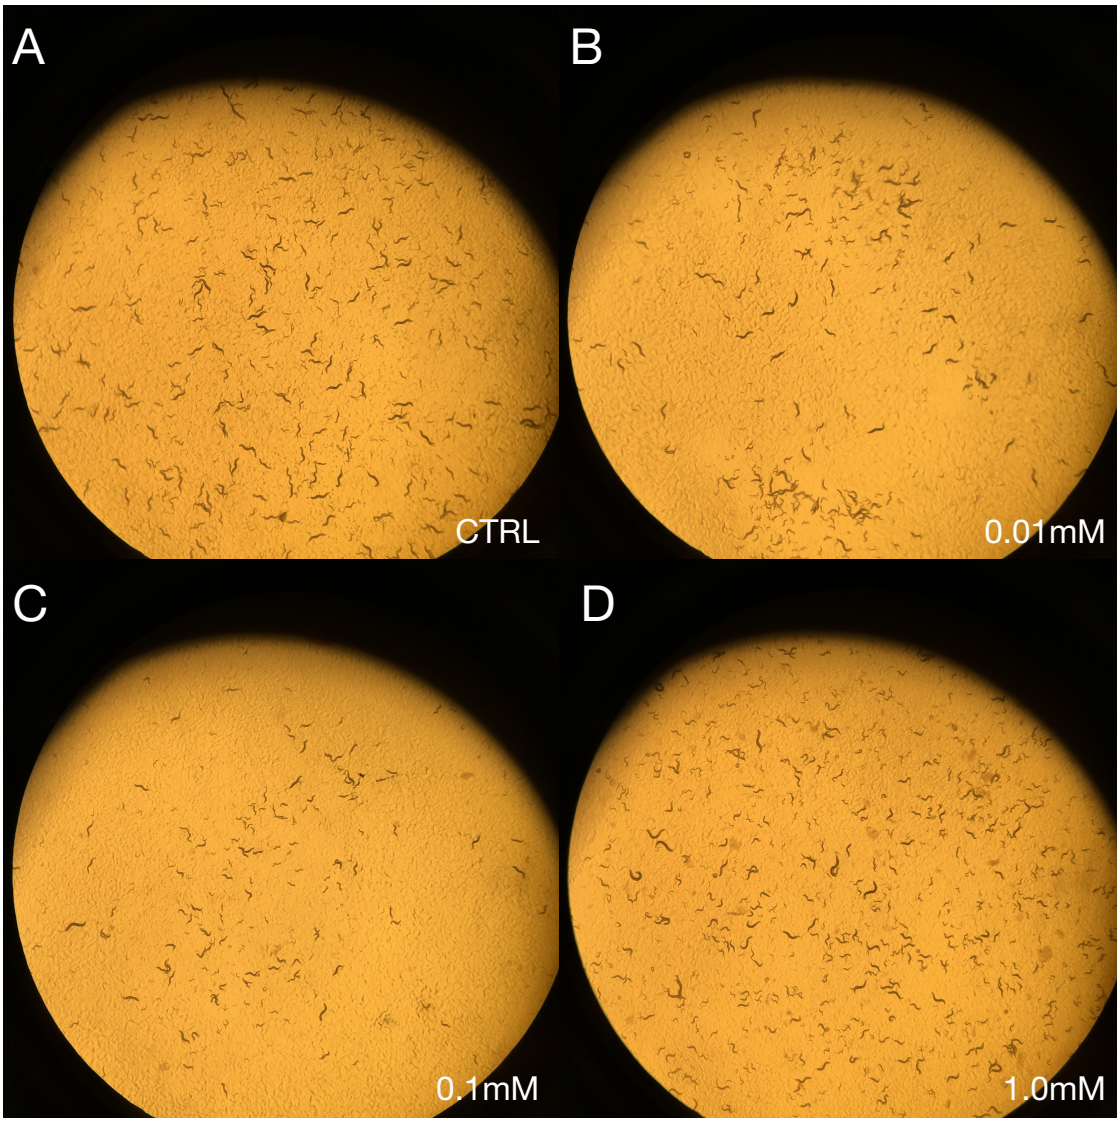

Figure 9.2 Colony Formation After UTX-1 Somatic Depletion.

Somatic depletion of UTX-1 appears to have only a subtle effect on population growth. Images taken using a dissecting microscope 5 days after seeding each plate with an initial 10 animals at the L4 stage.

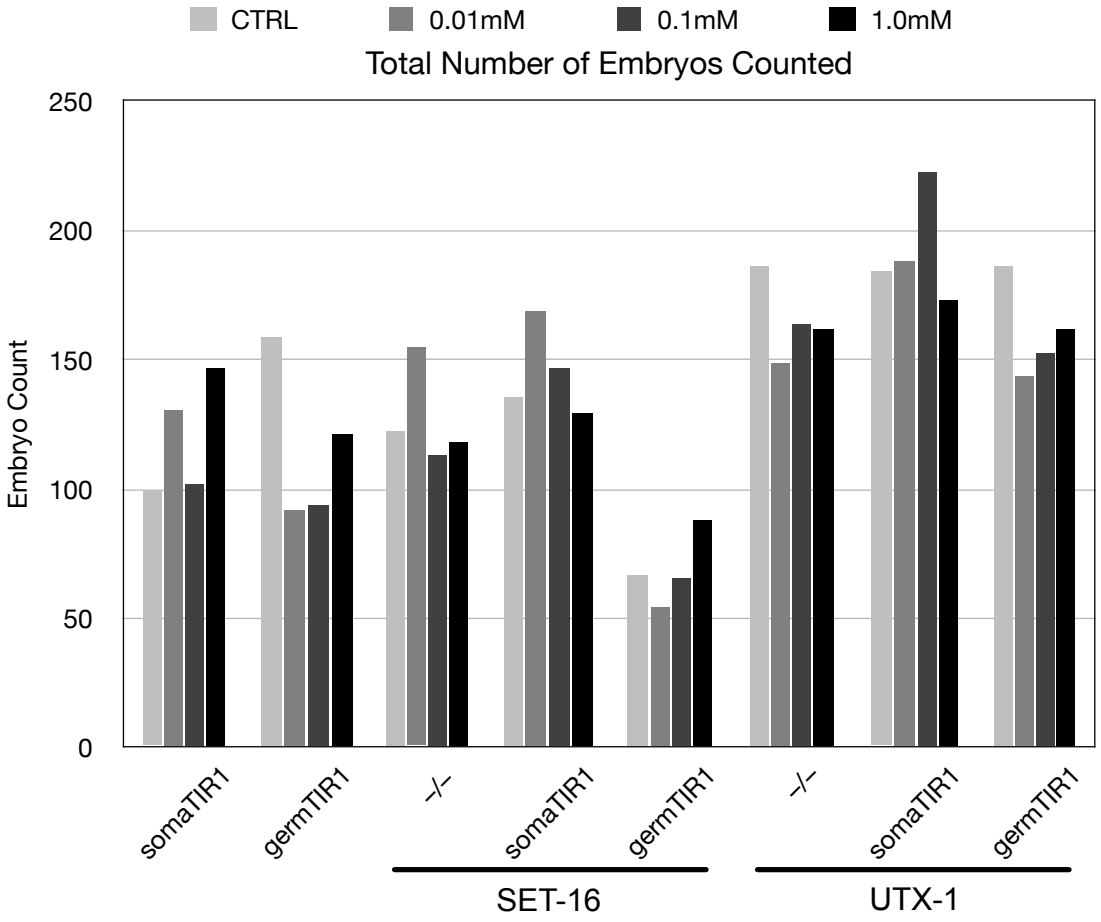

Figure 10.1 Total Embryo Counts Across a Range of Auxin Concentrations

Total number of embryos counted for both somatic and germline depletion strains after seeding with a total of four L4 progenitors across four auxin concentrations. Embryos were counted 24 hours after initial transfer of animals. The SET-16 germline depletion strain produced the fewest number of embryos at any concentration, including 0.0mM auxin.

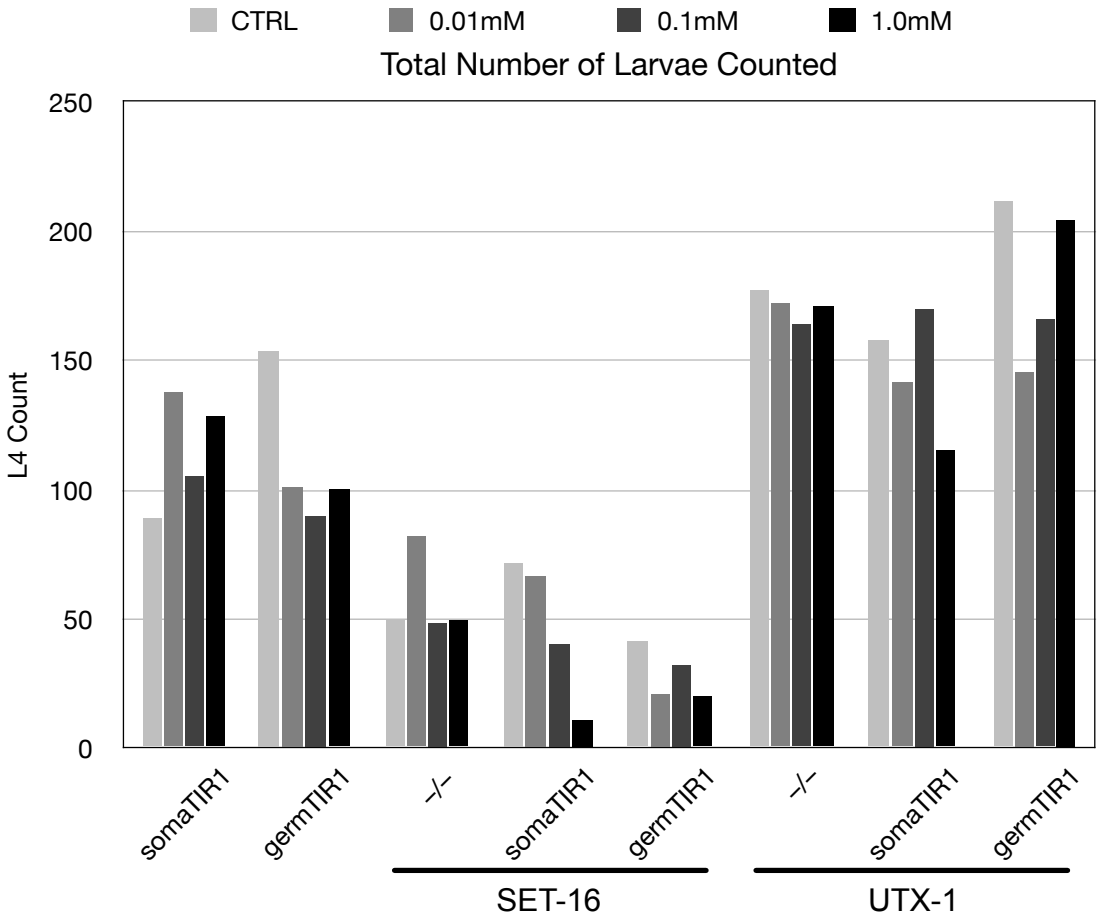

Figure 10.2 Total Larvae Count Across a Range of Auxin Concentrations

Total number of larvae to reach the L4 stage of development counted for both somatic and germline strains after seeding with a total of four L4 progenitors across four auxin concentrations. AID-GFP tagged SET-16 animals produce the fewest viable larvae overall and show the most significant response to elevated concentrations of auxin.

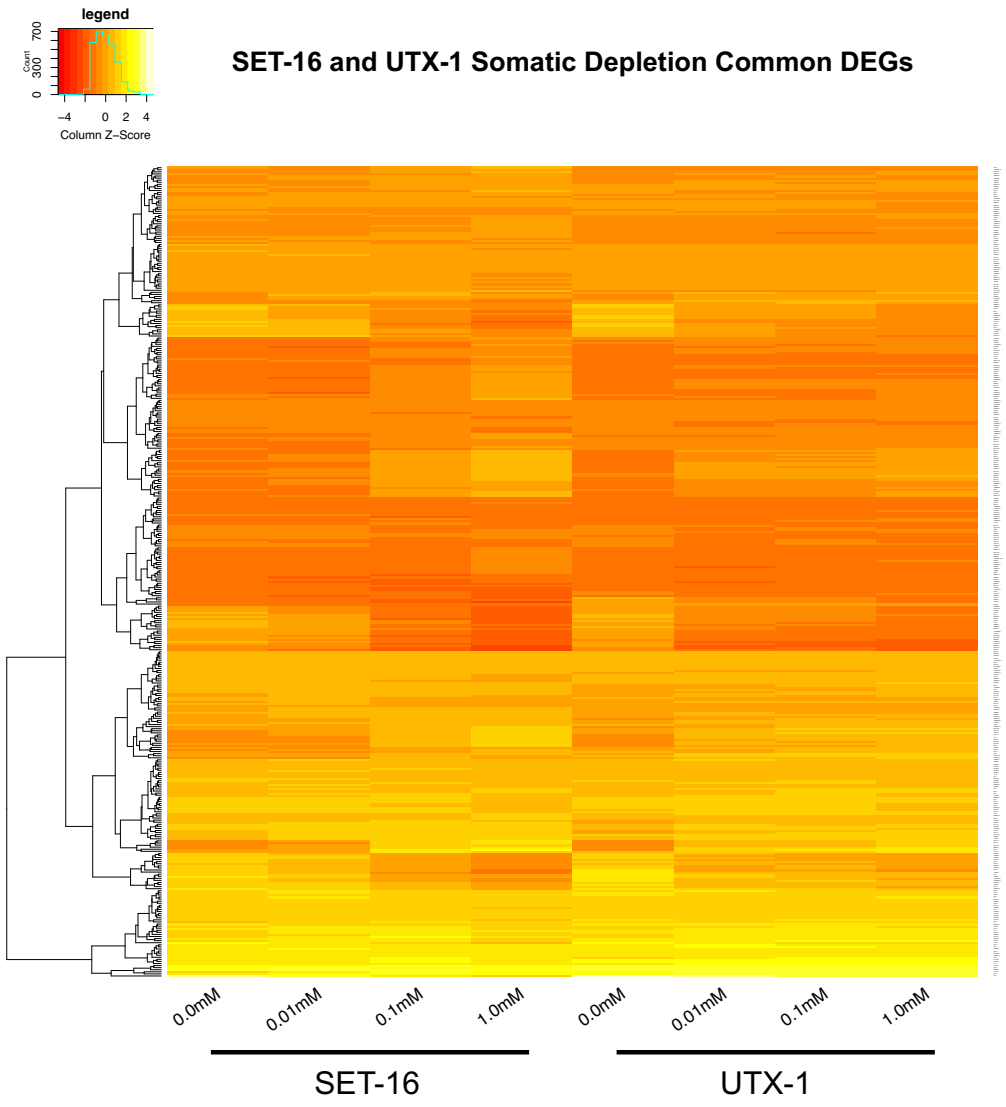

Figure 11. Somatic Depletion of SET-16 and UTX-1 Identifies Common Differentially Expressed Genes (DEGs).

Normalized baseline gene expression of 390 common DEGs (differentially expressed genes) per three auxin conditions compared to control standard of genomic expression. 61 common DEGs were found to be significantly down-regulated as a result of auxin induced depletion of either SET-16 or UTX-1 while 329 common DEGs were found to be significantly up-regulated as a result of the same induced depletion. Figure and statistical data compiled using RStudio v1.2.5001.

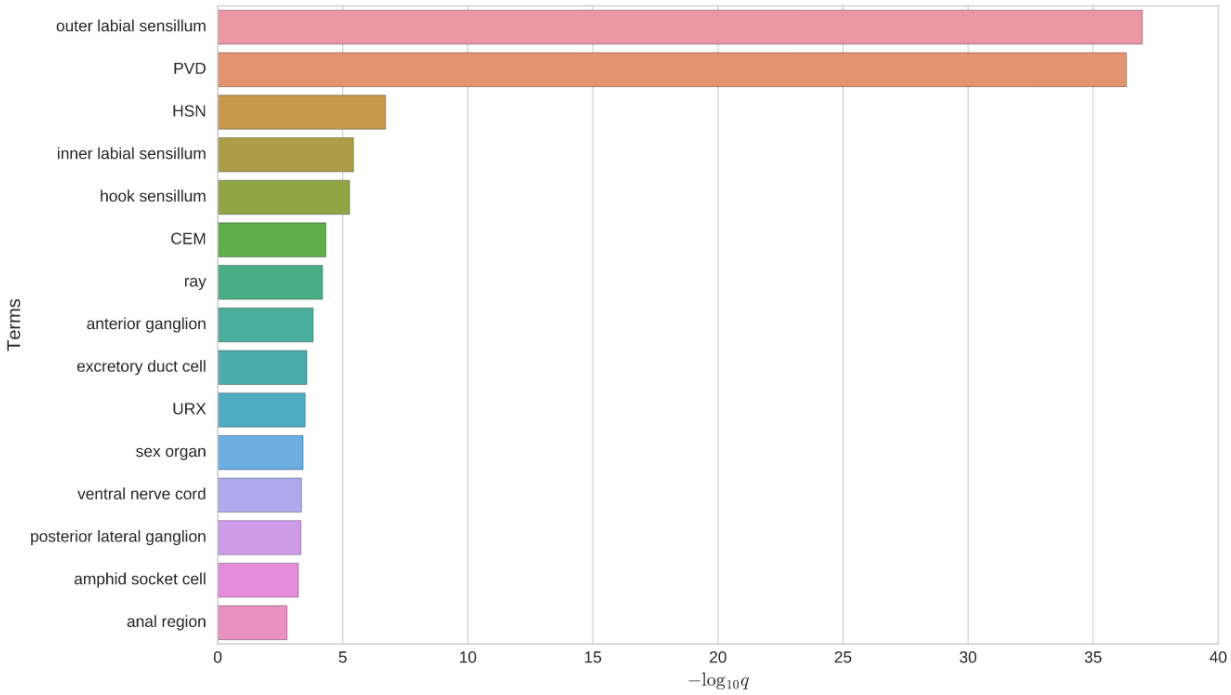

Figure 12.1. Up-Regulated Gene-set Enrichment for Somatic Depletion of SET-16.

Gene-set enrichment test for up-regulated DEGs in response to somatic depletion of SET-16 show a higher number of genes related to development of the outer labial sensilla and PVD neurons are effected. Scales indicate log10 q-values. Figure compiled via wormbase.org enrichment test program, courtesy of Dr. Jaejoon Choi and Dr. Alice Lee.

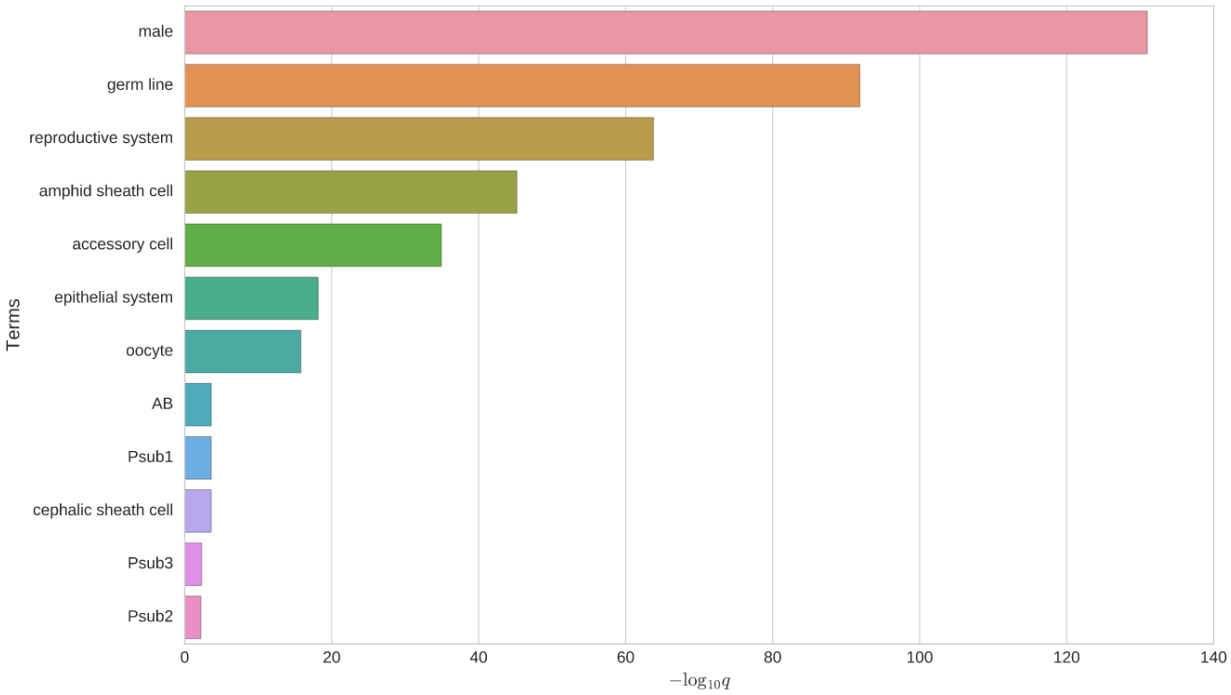

Figure 12.2. Down-Regulated Gene-set Enrichment for Somatic Depletion SET-16.

Gene-set enrichment test for down-regulated DEGs in response to somatic depletion of SET-16 show a high number of genes related to male phenotypes as well as germline and reproductive system development are effected. Scales indicate log10 q-values. Figure compiled via wormbase.org enrichment test program, courtesy of Dr. Jaejoon Choi and Dr. Alice Lee.

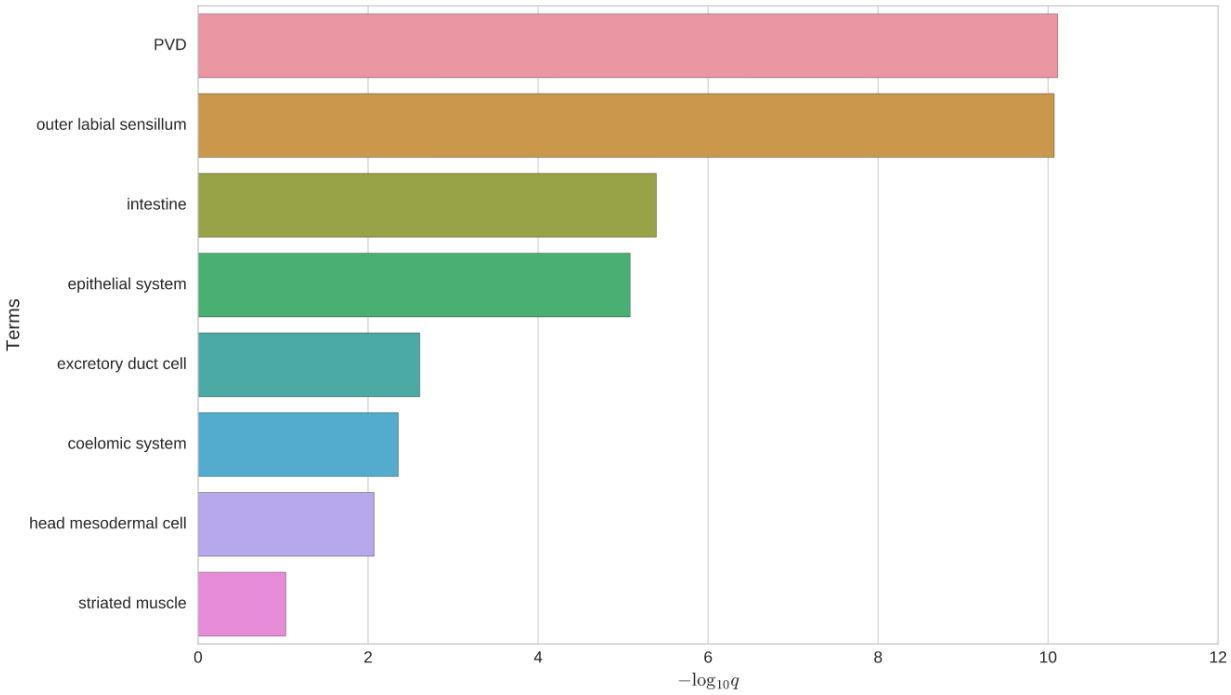

Figure 13.1. Up-Regulated Gene-set Enrichment for Somatic Depletion of UTX-1.

Gene-set enrichment test for up-regulated DEGs in response to somatic depletion of UTX-1 show a higher number of genes related to development of the outer labial sensilla and PVD neurons are effected, similar to somatic depletion of SET-16. Scales indicate log10 q-values. Figure compiled via wormbase.org enrichment test program, courtesy of Dr. Jaejoon Choi and Dr. Alice Lee.

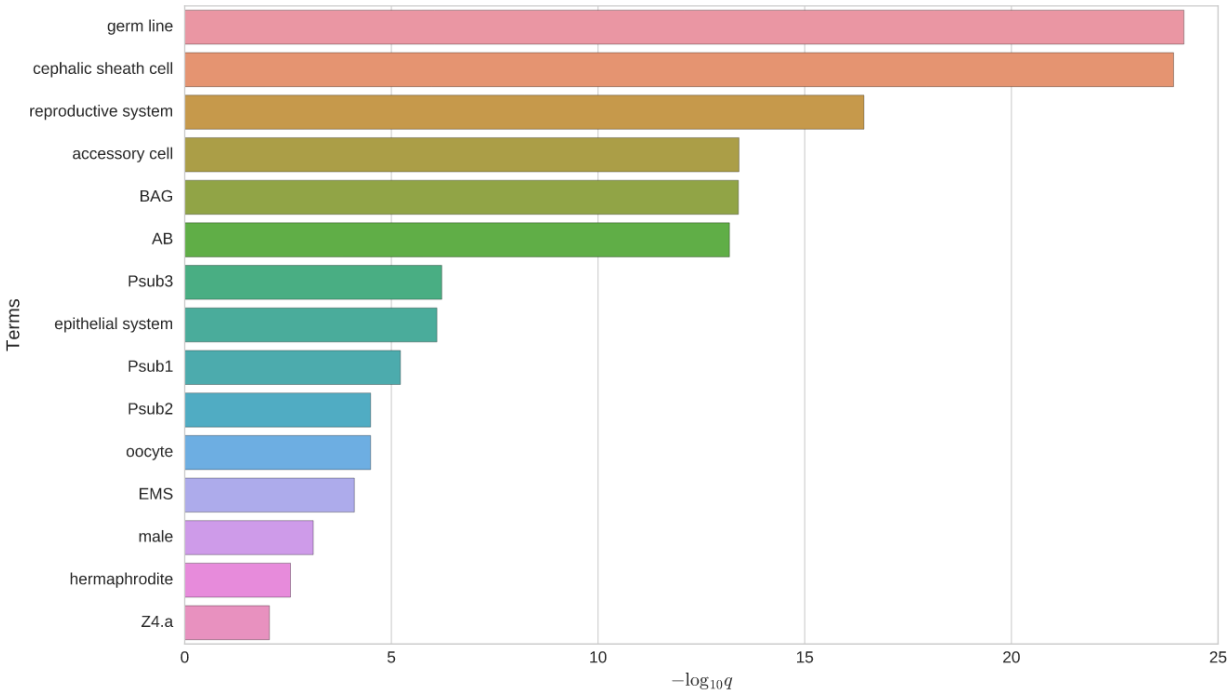

Figure 13.2. Down-Regulated Gene-set Enrichment for Somatic Depletion UTX-1.

Gene-set enrichment test for down-regulated DEGs in response to somatic depletion of UTX-1 show a higher number of genes related germline and reproductive system development, as well as cephalic sheath are effected. Scales indicate log10 q-values. Figure compiled via wormbase.org enrichment test program, courtesy of Dr. Jaejoon Choi and Dr. Alice Lee.

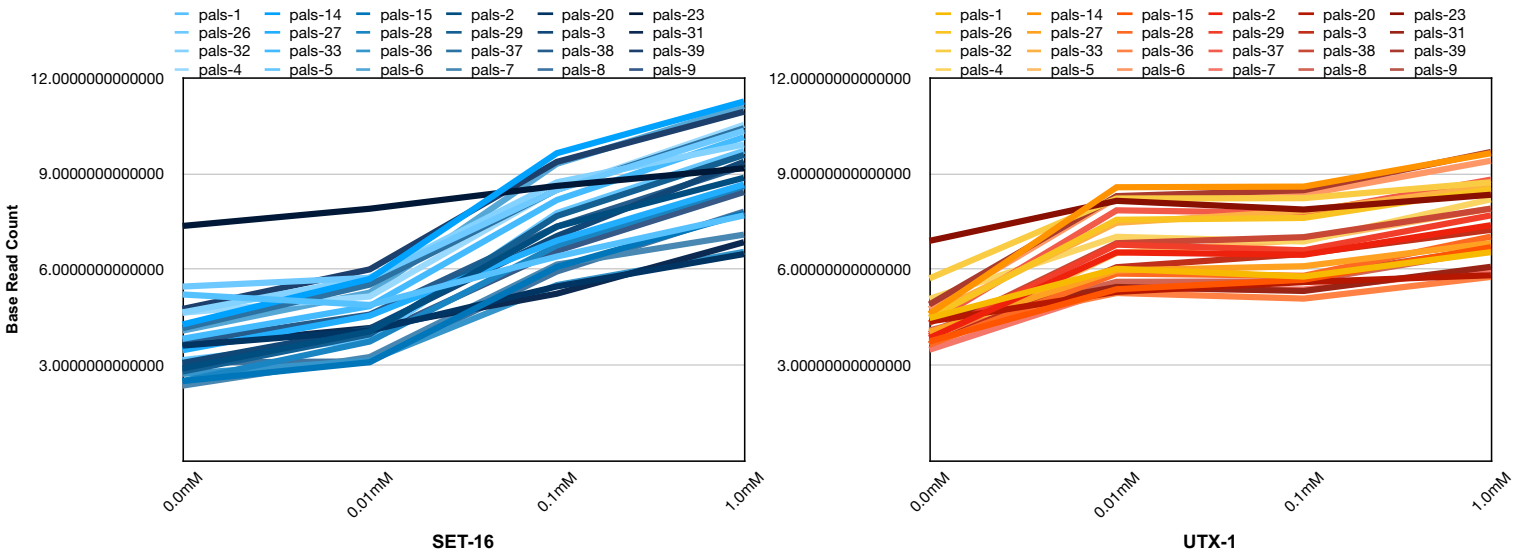

Figure 14. SET-16 and UTX-1 Somatic Depletion Commonly Upregulates 24 out of 39

Members of the Protein Containing ALS2cr12 Signature ("*pals*-") Family.

Line graphs depicting similar response curves from members of the pals family of genes between SET-16 (left) and UTX-1 (right) somatic depletions across a range of auxin concentrations. SET-16 somatic depletion has a greater effect, producing a steeper response curve than UTX-1 somatic depletions. Base read counts calculated from the average base reads per three replicates. Individual values can be found in Supplemental Table Data S1. below. Figures compiled using Numbers v10.1 (6913).

Supplemental Table Data.

Table S1. SET-16/SomaTIR1 and UTX-1/SomaTIR1 Common DEGs.

A total of 61 commonly down-regulated and 329 commonly up-regulated genes from both SET-16/SomaTIR1 and UTX-1/SomaTIR1 depletion experiments are listed in order from SET-16 (left) to UTX-1 (right). Two genes, nas-24 and F25E5.7 (red box), do not share the same response trend per depletion. WormBase Gene IDs are listed at left followed by actual gene name. Numbers indicate mean base read count. Log2FoldChange was calculated from the overall change in expression across three auxin concentrations compared to control. Table data assembled using Numbers v10.1 (6913).

Supplemental Figure Data.

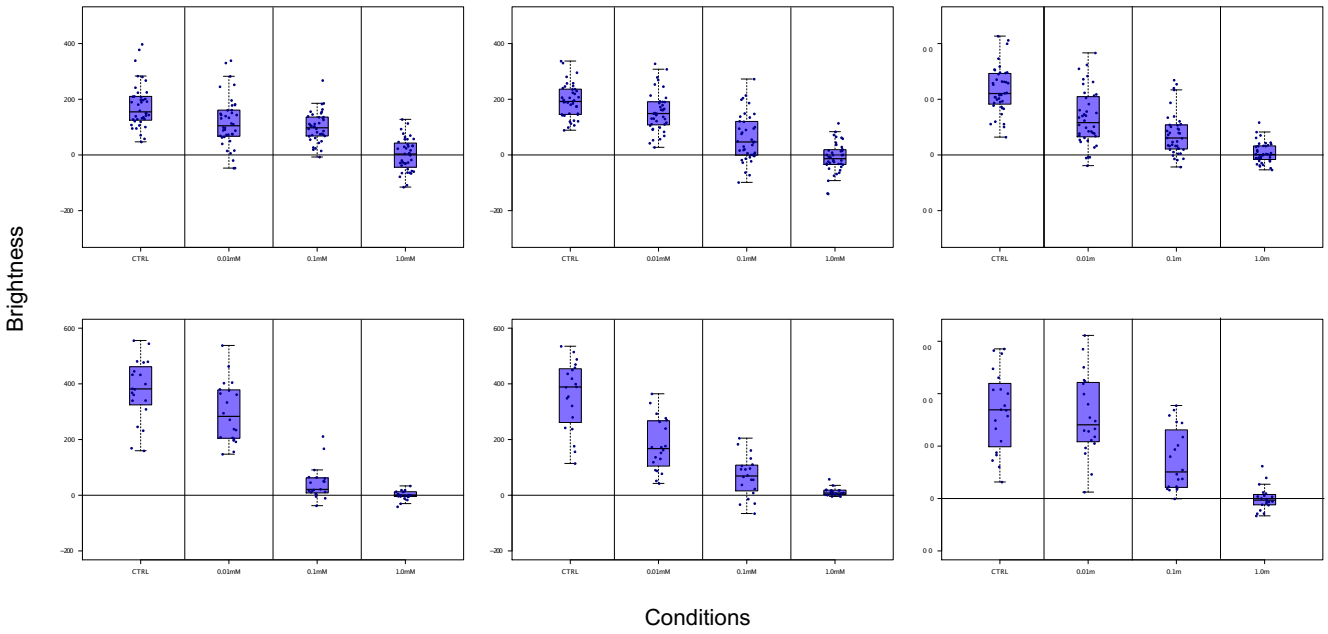

Figure S1. Individual Replicates for Germline and Somatic Depletions of SET-16.

GFP fluorescence intensity across auxin concentrations of ieSi64II;set-16(syb1046)III oocyte nuclei and ieSi57II;set-16(syb1046)III somatic cells (n=40 per condition per replicate for germline and n=20 per condition per replicate for soma). Data points indicate mean pixel intensity calculated by the difference in nuclear GFP from background. Replicates for germline (top) and somatic (bottom) strains are shown in order from left to right.

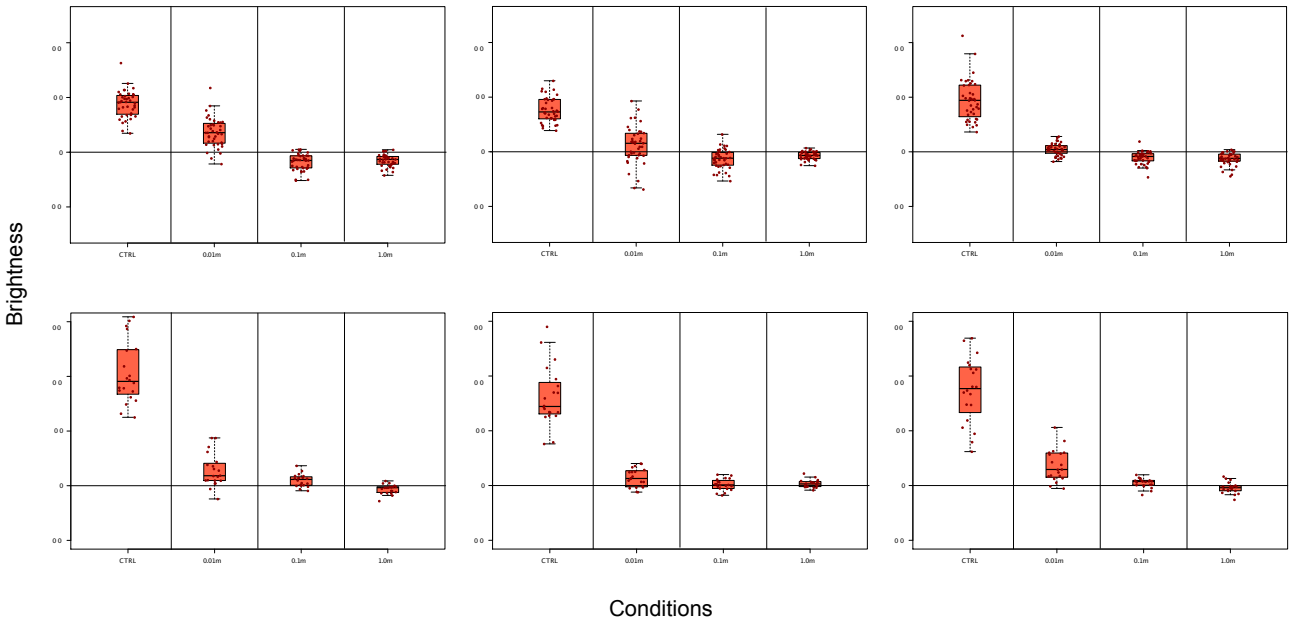

Figure S2. Individual Replicates for Germline and Somatic Depletions of UTX-1.

GFP fluorescence intensity across auxin concentrations of utx-1(syb1026)X;ieSi38IV oocyte nuclei and ieSi57II;utx-1(syb1026)X somatic cells (n=40 per condition per replicate for germline and n=20 per condition per replicate for soma). Data points indicate mean pixel intensity calculated by the difference in nuclear GFP from background. Replicates for germline (top) and somatic (bottom) strains are shown in order from left to right.
