Abstract

Evolutionary stability is a fundamental concept in evolutionary game theory. A strategy is called an evolutionarily stable strategy (ESS), if its monomorphic population rejects the invasion of any other mutant strategy. Recent studies have revealed that population structure can considerably affect evolutionary dynamics. Here we derive the conditions of evolutionary stability for games on graphs. We obtain analytical conditions for regular graphs of degree $k > 2$. Those theoretical predictions are compared with computer simulations for random regular graphs and for lattices. We study three different update rules: birth-death (BD), death-birth (DB), and imitation (IM) updating. Evolutionary stability on sparse graphs does not imply evolutionary stability in a well-mixed population, nor vice versa. We provide a geometrical interpretation of the ESS condition on graphs.

Key words: evolutionary game theory, evolutionary graph theory, ESS, structured population, spatial games
1 Introduction

Evolutionary game theory is the study of frequency dependent selection (Maynard Smith 1982, Hofbauer & Sigmund 1998, Nowak & Sigmund 2004, Nowak 2006). The fitness of an individual is not constant, but depends on interactions with other individuals. These interactions can be described by a game. The payoff from the game affects fitness, which is reproductive success. Reproduction can be genetic or cultural.

An important concept in evolutionary game dynamics is that of an evolutionarily stable strategy (ESS) (Maynard Smith & Price 1973, Maynard Smith 1974, 1982). If all players of a population adopt that strategy, then no mutant strategy can invade. The traditional ESS condition is defined for infinitely large, well-mixed populations. In a well-mixed population, every individual interacts with every other individual equally likely. Real populations are, of course, neither infinitely large nor well-mixed. Various attempts have been made to extend the ESS concept to populations of finite size (Maynard Smith 1988, Schaffer 1988, Ficici & Pollack 2000, Neill 2004, Nowak et al. 2004, Wild & Taylor 2004, Traulsen et al. 2006).

In spatial evolutionary game theory (Nowak & May 1992), the players of a population are arranged on a spatial grid and interact with their nearest neighbors. Spatial games can lead to very different evolutionary dynamics than games in well-mixed populations (Nowak & May 1992, 1993, Wilson et al. 1992, Ellison 1993, Herz 1994, Lindgren & Nordahl 1994, Nowak et al. 1994, Killingback & Doebeli 1996,

Evolutionary graph theory (Lieberman et al. 2005, Ohtsuki et al. 2006, Ohtsuki & Nowak 2006a,b, Pacheco et al. 2006a,b, Taylor et al. 2007) is the extension of spatial evolutionary dynamics to general graphs and networks. The members of a population occupy the vertices of a graph. Interactions occur between connected individuals. Many different update rules are possible. Competition for reproduction and playing the game can be described by the same graph or by two different graphs (Ohtsuki et al. 2006, Ohtsuki & Nowak 2006a,b, Ohtsuki et al. 2007a,b). A well-mixed population is defined by a complete graph with identical weights. Spatial games are typically described by regular lattices.

The purpose of this paper is to derive the ESS condition for games on graphs.
The paper is structured as follows. In Section 2, we review the definition of evolutionary stability in a well-mixed population. In Section 3, we introduce three different update rules and formulate the replicator equation on graphs (Ohtsuki & Nowak 2006b). Section 4 describes our main results. We give geometrical representations of the ESS conditions on graphs in Sections 5 and 6. We offer examples and computer simulations in Section 7. Finally, we provide a discussion in Section 8.

2 Evolutionary stability in a well-mixed population

Consider a game between two strategies, $A$ and $B$. The payoff matrix is given by

$$
\begin{pmatrix}
A & B \\
A & (a & b) \\
B & (c & d)
\end{pmatrix}.
$$

In a well-mixed population every player meets every other player equally likely. Let $x_A$ and $x_B$ be the frequencies of $A$ and $B$ players in the population. The average payoffs of $A$ and $B$ players are given by

$$
P_A = ax_A + bx_B$$

$$
P_B = cx_A + dx_B.
$$

A population of $A$ individuals is challenged by a small fraction of $B$ invaders. The relative abundance of $B$ players is $x_B = \epsilon$, where $0 < \epsilon \ll 1$. The fraction of $A$ players is $x_A = 1 - \epsilon$. Strategy $A$ is evolutionary stable if $P_A > P_B$ for
\[(x_A, x_B) = (1 - \epsilon, \epsilon).\] This condition leads to

\[(a - c)(1 - \epsilon) + (b - d)\epsilon > 0. \quad (3)\]

For \(\epsilon \to 0\), the left hand side of (3) is positive if and only if

\[
\text{ESS: } \quad \begin{cases} a > c \quad \text{or} \quad a = c \quad \text{and} \quad b > d. \end{cases} \quad (4)
\]

The condition, \(b > d\), is only used in the knife-edge case, \(a = c\).

The evolutionary stability of a strategy in a game with \(n\) strategies can be defined in a similar way. A strategy is ESS if and only if condition (4) holds in pairwise comparison with each of the \(n - 1\) other strategies.

The traditional stability concept in game theory is the Nash equilibrium (Nash 1950, Luce & Raiffa 1957, Fudenberg & Tirole 1991, Binmore 1994, Weibull 1995, Samuelson 1997). For payoff matrix (1), strategy \(A\) is called a ‘Nash equilibrium’ if and only if

\[
\text{Nash: } \quad a \geq c. \quad (5)
\]

Condition (5) implies that \(A\) is a best reply to itself. In addition, strategy \(A\) is called a ‘strict Nash equilibrium’ if and only if

\[
\text{Strict Nash: } \quad a > c. \quad (6)
\]

Condition (6) implies that \(A\) is the unique best response to itself. Note that if \(A\) is a strict Nash equilibrium then it is an ESS. If \(A\) is an ESS then it is a Nash equilibrium.

While the condition for a Nash equilibrium depends only on the payoff matrix, a

3 Evolutionary game dynamics on graphs

In this section, we introduce three different update rules for evolutionary games on graphs (Ohtsuki et al. 2006, Ohtsuki & Nowak 2006a,b). Then we discuss the ‘replicator equation on graphs’ (Ohtsuki & Nowak 2006b).

We consider an infinitely large population. The structure of the population is described by an infinite, connected, and regular graph of degree $k$. A graph is called ‘regular’ when each node has exactly the same number of neighbors; that number is called the ‘degree’ of the graph. Each node represents a player whose strategy is either $A$ or $B$. There are no empty nodes. In this paper, we study $k > 2$. For games on cycles, $k = 2$, we refer to Ohtsuki & Nowak (2006a).

Each player interacts with all $k$ neighbors, and obtains an accumulated payoff, denoted by $P$. The accumulated payoff is translated into fitness, $F$, by the following formula:

$$ F = (1 - w) + w \cdot P. \quad (7) $$

Here $0 \leq w \leq 1$ represents the intensity of selection. If $w = 0$ then fitness is constant, $F = 1$, and independent of the payoff. Throughout the paper, we consider
the case of small $w$, given by $0 < w \ll 1$.

Given the fitnesses of all players, we update the strategy of one player in each elementary time step. Therefore updating is asynchronous. We consider the following three update rules (Ohtsuki et al. 2006, Ohtsuki & Nowak 2006a,b):

- **Birth-Death (BD) updating.** An individual is chosen for reproduction proportional to fitness; the offspring replaces a randomly chosen neighbor.

- **Death-Birth (DB) updating.** A random individual is chosen to die; the $k$ neighbors compete for the empty site proportional to their fitness.

- **Imitation (IM) updating.** A random player is chosen for updating his strategy; he either adopts a strategy of one of his $k$ neighbors or remains with his own strategy, proportional to fitness.

Using the pair approximation method (Matsuda et al. 1987, 1992, Nakamaru et al. 1997, 1998, Keeling 1999, van Baalen 2000), Ohtsuki & Nowak (2006b) have shown that for small $w$ the frequencies of strategies on a regular graph of degree $k$ can be described by a differential equation. For a $n \times n$ game with the payoff matrix, $[a_{ij}]$, it is given by

\[
\dot{x}_i = x_i \left[ \sum_{j=1}^{n} x_j (a_{ij} + b_{ij}) - \phi \right].
\]  

(8)

Here $x_i$ denotes the frequency of $i$-th strategy, a dot represents time derivative, and $\phi = \sum_{i,j=1}^{n} x_i x_j (a_{ij} + b_{ij})$. For each update rule, the value of $b_{ij}$ in eq.(8) is
calculated from the original payoff matrix, \([a_{ij}]\), as

\[
\begin{align*}
\text{BD : } b_{ij} &= \frac{a_{ii} + a_{ij} - a_{ji} - a_{jj}}{k - 2} \\
\text{DB : } b_{ij} &= \frac{(k + 1)a_{ii} + a_{ij} - a_{ji} - (k + 1)a_{jj}}{(k + 1)(k - 2)} \\
\text{IM : } b_{ij} &= \frac{(k + 3)a_{ii} + 3a_{ij} - 3a_{ji} - (k + 3)a_{jj}}{(k + 3)(k - 2)}.
\end{align*}
\tag{9}
\]

Interestingly, differential equation (8) has the form of a replicator equation (Taylor & Jonker 1978, Hofbauer et al. 1979, Zeeman 1980, Weibull 1995, Hofbauer & Sigmund 1998, Nowak 2006) with a transformed payoff matrix, \([a_{ij} + b_{ij}]\). Therefore, many aspects of evolutionary dynamics on graphs can be analyzed by studying a standard replicator equation with a transformed payoff matrix, a so-called ‘replicator equation on graphs’. For example, for the 2 × 2 payoff matrix, (1), Ohtsuki & Nowak (2006b) have shown that the transformed payoff matrix is

\[
\begin{pmatrix}
A & B \\
A & a & b + h \\
B & c - h & d
\end{pmatrix}
\tag{10}
\]

The modifier \(h\) depends on the update rule. It is given by

\[
\begin{align*}
\text{BD : } h &= \frac{a + b - c - d}{k - 2} \\
\text{DB : } h &= \frac{(k + 1)a + b - c - (k + 1)d}{(k + 1)(k - 2)} \\
\text{IM : } h &= \frac{(k + 3)a + 3b - 3c - (k + 3)d}{(k + 3)(k - 2)}.
\end{align*}
\tag{11}
\]

These results hold for infinitely large population size and for \(0 < w \ll 1\). Regarding a finite population of size \(N\), Ohtsuki & Nowak (2006b) found that the
replicator equation on graphs gives a good approximation if $Nw \gg 1$.

In the next section, we use eqs.(10) and (11) to derive the concept of evolutionary stability for graph selection.

4 ESS conditions on graphs

In order to characterize evolutionary stability on graphs, we ask whether rare mutants (of $\epsilon$ fraction) have an selective advantage over residents. According to the modified payoff matrix (10), if $a > c - h$ then rare $B$ mutants are selected against in an $A$-population. In this case, $A$ is ESS when compared to $B$. If $a < c - h$ then $B$ can invade $A$ and, therefore, $A$ is not an ESS. We do not discuss the evolutionary stability of the ‘knife-edge’ case, $a = c - h$, because it is ungeneric. Throughout the paper we call

$$\textbf{ESS on graphs: } a > c - h.$$ (12)

the ‘ESS condition on graphs’.

In contrast to the ESS condition on graphs, the conditions for (strict) Nash equilibrium on graphs are not obtained from the modified payoff matrix, (10). By analogy to its counterpart in a well-mixed population, a straightforward definition of (strict) Nash equilibrium on graphs is as follows: a strategy is a (strict) Nash equilibrium on graphs if no one gains a (strictly) higher payoff by switching to the other strategy. Therefore, the conditions for (strict) Nash equilibrium on graphs are the same as those in a well-mixed population, eqs.(5, 6). On graphs, it is possible that a strict
Nash equilibrium is not an ESS. It is also possible that an ESS is not a Nash equilibrium. We will discuss this issue further in Section 7.1.

For the three update rules, condition (12) is rewritten as follows:

**ESS on graphs (BD updating):**

\[(k - 1)a + b > (k - 1)c + d\]  \hfill (13)

**ESS on graphs (DB updating):**

\[(k^2 - 1)a + b > (k^2 - k - 1)c + (k + 1)d\]  \hfill (14)

**ESS on graphs (IM updating):**

\[(k^2 + 2k - 3)a + 3b > (k^2 + k - 3)c + (k + 3)d\]  \hfill (15)

All these conditions converge to \(a > c\) for \(k \to \infty\). This makes sense, because a well-mixed population is described by a fully connected graph.

5 The geometry of evolutionary stability

We can provide a beautiful geometrical representation of the ESS conditions (13-15). Figure 1 illustrates the invasion of a homogeneous \(A\) population by an \(\epsilon\) fraction of \(B\) players. Initially the \(B\) players are sprinkled randomly over the entire population: each vertex changes from \(A\) to \(B\) with probability \(\epsilon\), which is very
small. The following evolutionary dynamics have two time scales: (i) on a fast
time scale the population ‘equilibrates’ locally and $B$-clusters are formed, (ii) on a
slower time scale the global frequency of $A$ (and $B$) is changing. This separation
of time scales is a consequence of the weak intensity of selection, $0 < w \ll 1$
(Ohtsuki et al. 2006).

After the local equilibration process, we find that, a $B$ player, whose one neighbor is
already specified, has on average one $B$ neighbor among his $k - 1$ other neighbors.
Thus, in order to intuitively understand the ESS conditions on graphs, (13-15), it is
convenient to use a schematic drawing where a half-line of $B$ players is embedded
in a sea of $A$ players (Fig. 2). If the tip of the half-line is more likely to shrink than
to extend, then $A$ is ESS. Otherwise selection favors the invasion of $B$.

For example, let us study the invasion dynamics for $DB$ updating. The half-line of
$B$-players extends in length by one if (i) one of the $(k - 1)$ $A$-neighbors of the $B$-
player on the tip is chosen to die and (ii) the $B$-player, whose payoff is $(k - 1)c + d$,
wins the competition over the vacancy against $(k - 1)$ $A$-players, whose payoff is
$ka$. These events occur with a probability that is proportional to

$$
(k - 1) \cdot \frac{(1 - w) + w\{(k - 1)c + d\}}{[(1 - w) + w\{(k - 1)c + d\}] + (k - 1)(1 - w) + w \cdot ka} \tag{16}
$$

A similar calculation shows that the half-line of $B$-players shrinks in length by one
with a probability proportional to (up to the same constant)

$$
1 \cdot \frac{(k - 1)[(1 - w) + w\{(k - 1)a + b\}]}{(k - 1)[(1 - w) + w\{(k - 1)a + b\}] + [(1 - w) + w\{(k - 2)c + 2d\}]} \tag{17}
$$
For small $w$, it is easy to see that probability (16) being smaller than probability (17) is equivalent to the ESS condition for DB updating, (14). The ESS conditions for BD and IM updating rules, (13) and (15), can be derived in the same way.

6 Intuitive counting over one contested edge

There is a simple, intuitive way to derive the ESS conditions on graph, (13-15). Again we consider the tip of the half-line of $B$ players. The trick to derive the ESS conditions, (13-15), is to sum up the payoffs of all players involved in the movement of an edge extending from the tip (=a boundary between $A$ and $B$ players), but separately for $A$-players and for $B$-players. Then we compare these total payoffs to see which replacement is more likely to occur at the boundary. If the total payoff of strategy $A$ exceeds that of $B$, then strategy $A$ is an ESS on graphs.

Figure 3 shows the calculation for birth-death (BD) updating. The two players at the boundary are involved in the contest (they are marked with circles). The $A$-player has payoff $(k - 1) + b$. The $B$-player has payoff $(k - 1)c + d$. Comparison of these two payoffs immediately leads to the ESS condition for BD updating, (13).

Figure 4 describes death-birth (DB) updating. We focus on the movement of the boundary which is shown as a dotted line. There are two possibilities.

(i) If the $A$-player at the boundary dies (top panel), his $(k - 1) A$-neighbors and one $B$-neighbor compete for the empty site. Each of the $(k - 1) A$-neighbors has
payoff $ka$, and has one $B$-opponent. The $B$-player has payoff $(k - 1)c + d$. He has $(k - 1)$ $A$-opponents. Therefore, his ‘weight’ is $k - 1$.

(ii) If the $B$-player at the boundary dies (bottom panel), one $A$-neighbor and one $B$-neighbor (marked with circles) are relevant for the movement of the boundary. Notice that other $A$-neighbors are NOT involved in the movement of the boundary, because if one of them replaces the vacancy a different boundary moves.

The $A$-player has payoff $(k - 1)a + b$ and has one $B$-opponent. The $B$-player has payoff $(k - 2)c + 2d$ and has one $A$-opponent.

Comparing the two weighted total payoffs reproduces our ESS condition for DB updating, (14). Figure 5 shows how to derive the ESS condition for IM updating.

7 Numerical examples and computer simulations

7.1 Examples

We will now study some examples, which elucidate the difference between ESS in well mixed populations and on sparse graphs.
Let us first consider the following game:

\[
\begin{pmatrix}
A & B \\
A & 1 & 3 \\
B & 2 & 0
\end{pmatrix}.
\] (18)

In this example, strategy A is not an ESS in a well-mixed population. However, it is an ESS on a regular graph of degree \( k = 3 \) for all update rules (BD, DB, and IM).

The reason for this discrepancy between well-mixed populations and graph-structured populations can be understood as follows. Imagine that strategy A dominates the population and that a B-mutant tries to invade it. The average payoff of the B-mutant per game is 2. In a well-mixed population, the average payoff of A players is 1. Hence, strategy A is not evolutionarily stable. However, in a graph-structured population, the payoff of the A-neighbors of the B-mutant affects selection. These A-neighbors gain payoff, 3, from the interaction with the B-mutant, which exceeds the mutant’s payoff, 2. Therefore, the B-mutant fails to invade the population.

The game (18) is an example where strategy A is not a Nash equilibrium, but is an ESS on graphs.

As a second example, consider the game:

\[
\begin{pmatrix}
A & B \\
A & 2 & 0 \\
B & 1 & 3
\end{pmatrix}.
\] (19)

Strategy A is an ESS in a well-mixed population. However, it is not an ESS on a
regular graph of degree \( k = 3 \) for all three update rules (BD, DB, and IM).

Imagine that \( A \) players dominate the population. Their payoff per game is 2. When a \( B \) mutant invades the population, his payoff per game is 1. Therefore, strategy \( A \) resists invasion by strategy \( B \) in a well-mixed population. However, we notice that \( A \) players in the neighborhood of the invading \( B \)-player gain payoff, 0, from the game with \( B \). Strategy \( B \) considerably reduces the payoff of its \( A \)-neighbors. On graphs it can be adaptive to weaken neighbors with whom one competes (Nakamaru et al. 1997, Nakamaru & Iwasa 2005).

The payoff matrix (19) is an example for a game where strategy \( A \) is a strict Nash equilibrium, but is not an ESS on graphs.

As a third example, consider the Prisoner’s Dilemma game (Rapoport & Chammah 1965, Axelrod & Hamilton 1981). Cooperation (\( C \)) costs \( c \) for the donor and yields benefit, \( b \), for the recipient. Defection (\( D \)) yields zero payoff to both players. The payoff matrix is

\[
\begin{pmatrix}
C & D \\
C \begin{pmatrix} b - c & -c \\
D \begin{pmatrix} b & 0 \\
\end{pmatrix}
\end{pmatrix}
\end{pmatrix}
\]

(20)

In a well-mixed population, defection (\( D \)) is the unique ESS of the game. It is also true for games on graphs under BD updating. However, as is shown in Ohtsuki & Nowak (2006b), cooperation is the only ESS on a graph of degree \( k \) under DB updating whenever \( b/c > k \) is satisfied. For IM updating, \( b/c > k + 2 \) is the decisive condition for cooperation to be the unique ESS on graphs.
For the more general Prisoner’s Dilemma payoff matrix,

\[
\begin{pmatrix}
    C & D \\
    C & R & S \\
    D & T & P
\end{pmatrix},
\]

where \( T > R > P > S \), it is possible that both cooperation and defection are ESSs on graphs. It is also possible that neither of them is an ESS on graphs (see Ohtsuki & Nowak (2006b)) depending on the parameter values and the degree of the graph, \( k \).

7.2 Computer simulations

In order to test the validity of our analytic results, eqs.(13-15), we have run extensive computer simulations for each of the three update rules. We have studied random regular graphs of degrees \( k = 3, 4, 5, 6 \) and lattices of degrees \( k = 3, 4, 6 \).

We study a population of size \( N = 10^4 \). At the beginning of each run, 100 random vertices are changed for \( A \) to \( B \). We run simulations for 5 generations, or equivalently, \( 5N \) asynchronous updating steps. This means that each player in the population experiences, on average, 5 potential updating events. After 5 generations, we count the number of \( B \) players in the population. We conducted simulations \( 10^4 \) times for each set of parameters. Each data point in our result represents the average number of \( B \) players after 5 generations over \( 10^4 \) runs. In studying random regular graphs, we generate a new graph every \( 10^2 \) runs, in order to avoid the effect of a
particular configuration of a graph. Throughout our simulations, we use $w = 0.01$. Therefore we have $Nw = 100$, which meets the requirement of $Nw \gg 1$.

Figure 6 shows the result of computer simulations for random regular graphs. Note that the analytic predictions, eqs.(13-15), agree well with the simulations. Each column of panels in Figure 6 corresponds to one of the three update rules, BD (left), DB (center), and IM (right). In the upper three panels, we study the payoff matrix, $(a, b, c, d) = (0, b, 1, 0)$. Equations (13-15) predict that strategy $A$ is an ESS if

$$\text{BD : } b > k - 1$$
$$\text{DB : } b > k^2 - k - 1$$
$$\text{IM : } b > \frac{k^2 + k - 3}{3}. \tag{22}$$

In the lower three panels, we study $(a, b, c, d) = (1, 0, 0, d)$. In this case our predictions, eqs.(13-15), tell us that strategy $A$ is an ESS if

$$d < k - 1 \tag{23}$$

for all three update rules.

In Figure 7, we show the results of computer simulations for lattices of degrees $k = 3$ (triangular), $k = 4$ (square), and $k = 6$ (hexagonal). We find very good agreement between the simulations and the theoretical predictions for the triangular lattice, fairly good for the square lattice, but no good agreement for the hexagonal lattice.
The reason for this deviation can be understood as follows. The calculations of Ohtsu-ki & Nowak (2006b) are based on pair approximation, which is mathematically correct for Bethe lattices (= Cayley trees), that have no loops. However, both random regular graphs and lattices contain many loops. The existence of loops causes a discrepancy between simulation results and analytic conditions. The precision of the pair approximation depends on the length, $L$, of the existing loops. The smaller $L$ is, the worse pair approximation tends to be.

For Bethe lattices we have $L = \infty$. Thus pair approximation is correct. For large random regular graphs, $L$ is usually very large. For triangular, square, and hexagonal lattices, however, there are many loops with length $L = 6, 4$ and $3$, respectively (see Figure 8). Therefore, for those lattices we expect that predictions based on pair approximation do not work well.

8 Conclusion

We have derived ESS conditions for games on regular graphs of degree $k$. A resident strategy, $A$, can resist invasion by a small fraction of $B$ players if

\begin{align*}
\text{BD updating:} & \quad (k - 1)a + b > (k - 1)c + d \\
\text{DB updating:} & \quad (k^2 - 1)a + b > (k^2 - k - 1)c + (k + 1)d \quad (24) \\
\text{IM updating:} & \quad (k^2 + 2k - 3)a + 3b > (k^2 + k - 3)c + (k + 3)d
\end{align*}

The parameters, $a, b, c, d$, denote the entries of the payoff matrix, (1), which defines the game between strategies $A$ and $B$. The ESS conditions (24) hold for a weak
intensity of selection, $0 < w \ll 1$, and for infinitely large population size.

For well-mixed populations, which are given by the complete graph, $k \to \infty$, all three conditions converge to $a > c$. Thus, for infinite $k$, the decisive criterion is what does the resident get from itself, $a$, compared to what does the invader get from the resident, $c$. But for finite $k$, the payoff values $b$ and $d$ also matter; it is crucial to know, what the resident gets from the invader, $b$, and what the invader gets from itself, $d$.

For BD updating, $a$ is as important as $c$ (both parameters have the same weight, $k - 1$, in the ESS condition), and $b$ is as important as $d$. For DB and IM updating, however, $a$ is more important than $c$, and $b$ is less important than $d$. For all three update rules, we find that $a$ and $c$ enter into the ESS conditions with greater weights than $b$ and $d$.

The traditional ESS criterion of well-mixed populations is neither necessary nor sufficient to guarantee evolutionary stability in structured populations.

(panels in the center), and IM (panels in the right). In the top three panels, we study the parameter \((a, b, c, d) = (0, b, 1, 0)\) so \(b\) is the only free parameter, which is shown in each x-axis. In the bottom three, we study the parameters \((a, b, c, d) = (1, 0, 0, d)\), so \(d\) is the free parameter shown in each x-axis. The y-axis of each panel represents the average number of \(B\) players after 5 generations over \(10^4\) runs. In each small panel, the initial number of \(B\) players, that is \(n_B = 100\), is shown by the black horizontal dotted line. Thus, the number of \(B\) players after 5 generation being below this threshold, \(n_B = 100\), implies that strategy \(A\) is an ESS. For each degree \(k\), simulation results are plotted in a corresponding color with ‘x’-symbols. A colored vertical dotted line represents the theoretical prediction, eqs.(22-23). The simulation data show a perfect agreement with theoretical predictions if both data plots and a vertical dotted line in the same color intersect with the black horizontal dotted line exactly at the same point.

**Figure 7** The average number of \(B\) players after 5 generations, for lattices of degrees \(k = 3\) (triangular, in blue), \(k = 4\) (square, in green), and \(k = 6\) (hexagonal, in red). All the others conditions, such as update rules and parameters used, are the same and in the same order as in Figure 6. We find that results for hexagonal lattices (in red) show a particularly poor agreement with theoretical predictions.

**Figure 8** The length of the minimal loop, \(L\), is shown for triangular, square, and hexagonal lattices, respectively.

$\begin{align*}
(k-1)a + b \\
(k-1)c + d \\
(k-2)c + 2d
\end{align*}$
Birth-death (BD) updating

A is an ESS on graphs if

\[(k - 1)a + b > (k - 1)c + d\]

A payoff: \[\{(k - 1)a + b\} \times 1\]

B payoff: \[\{(k - 1)c + d\} \times 1\]
A payoff: \((k - 1) \times ka \times 1\)
B payoff: \(\{(k - 1)c + d\}\times (k - 1)\)

A is an ESS on graphs if
\[(k^2 - 1)a + b > (k^2 - k - 1)c + (k + 1)d\]

A payoff: \(\{(k - 1)a + b\}\times 1\)
B payoff: \(\{(k - 2)c + 2d\}\times 1\)
\[
\text{A payoff: } \begin{cases} 
(k - 1) \times ka \times 1 \\
\{(k - 1)a + b\} \times 1 
\end{cases} \\
\text{B payoff: } \begin{cases} 
\{(k - 1)c + d\} \times k 
\end{cases}
\]

A is an ESS on graphs if
\[
(k^2 + 2k - 3)a + 3b > (k^2 + k - 3)c + (k + 3)d
\]
