Abstract

Background—The role of weight training in the primary prevention of type 2 diabetes is largely unknown. We examined the association of weight training with risk of type 2 diabetes among U.S. men and assessed the influence of combining weight training and aerobic exercise.

Methods—We performed a prospective cohort study among 32,002 men from the Health Professionals Follow-up Study that were followed from 1990 until 2008. Weekly time spent on weight training and aerobic exercise (including brisk walking, jogging, running, bicycling, swimming, tennis, squash, calisthenics/rowing) was obtained from questionnaires at baseline and biennially during follow-up.

Results—During 508,332 person years of follow-up (18 years), we documented 2,278 new cases of type 2 diabetes. In multivariable adjusted models, we observed a dose-response relationship between an increasing amount of time spent on weight training or aerobic exercise and lower risk of diabetes (p for trend < 0.001). Engaging in weight training or aerobic exercise of at least 150 min/week was independently associated with a lower risk of diabetes of 34% (95% CI 7 – 54%) and 52% (95% CI 45 – 58%), respectively. Men who engaged in both aerobic exercise and weight training of at least 150 min/week had the greatest reduction in type 2 diabetes risk (59%, 95% CI 39 – 73%).

All authors have completed and submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. None of the authors have any conflict of interest to declare.

Conclusions—Weight training was associated with a significantly lower risk of type 2 diabetes, independent of aerobic exercise. The combination of weight training and aerobic exercise conferred a greater benefit.

Introduction

Regular physical activity (PA) is a cornerstone in the prevention and management of type 2 diabetes (T2DM). Achieving a daily amount of moderate or vigorous PA of at least 30 min/day is associated with a substantial reduction in the risk of T2DM.^{1–4} This is broadly consistent with the current recommendations on PA among adults.⁵ More recently, evidence from randomized controlled trials have shown that resistance training can improve glycemic control in patients with T2DM, even in the absence of aerobic training.⁶ This has led to the recommendation for resistance training 3 times per week among individuals with T2DM.^{7;8} However, whereas the evidence that regular aerobic exercise can prevent T2DM is compelling, to our knowledge, no previous studies have examined the role of weight training in the primary prevention of T2DM.

In this study we examined the association of weight training with the risk of T2DM among men followed biennially for 18 years in the Health Professionals Follow-up Study (HPFS). In particular, we examined whether the influence of weight training is independent of aerobic exercise and assessed the combined influence of weight training and aerobic exercise on T2DM risk.

Methods

Study population

The HPFS is an ongoing prospective cohort study of 51,529 male health professionals aged 40 to 75 years at baseline in 1986. Every two years the cohort participants are sent a questionnaire on diseases and personal- and lifestyle characteristics such as height, weight, smoking status, dietary intake (food frequency questionnaire (FFQ)), and PA. Ninety-four percent of the cohort has completed at least one follow-up questionnaire. For this analysis we excluded those men who reported a history of diabetes, cancer, myocardial infarction, angina, coronary artery bypass graft, other heart conditions, stroke, or pulmonary embolism on the baseline questionnaire (1986) and in 1988, and 1990, leaving a study population of 32,002 participants with information on exposures and covariates. This study was approved by the Harvard School of Public Health Institutional Review Board.

Assessment of weight training, other physical activity and TV viewing

From 1990 and onwards, the participants reported their average weekly amount of weight training, other physical activities, and TV viewing biennially. Other physical activities included walking, jogging, running, bicycling, swimming, tennis, squash, calisthenics/rowing, and heavy outdoor work. There were 13 response categories ranging from none to >40 hours/week for weight training and other PA's. Participants were also asked about the daily number of flights of stairs climbed, and usual walking pace. Of these other physical activities brisk walking, jogging, running, bicycling, swimming, tennis, squash, calisthenics/rowing was considered aerobic exercise of at least moderate intensity (≥ 3 METs). We used these activities because they are often performed repetitively and produce dynamic contractions of large muscle groups for an extended period of time.⁵ We calculated the total time spent on aerobic exercise of at least moderate intensity (≥ 3 METs) and grouped participants into four categories: none, 1–59, 60–149, and ≥ 150 min/week. We grouped participants in the same categories for weight training. We also constructed a variable representing unstructured PA of at least moderate intensity consisting of MET-hours per

week of activity heavy outdoor work and stair climbing as previously described.^{9,10} The reproducibility and validity of the PA questionnaire have been assessed in a sub-sample of the HPFS participants. The Pearson correlation between PA of vigorous intensity from diaries for 4 weeks across different seasons and that from the questionnaire was 0.58.¹¹ For weight training, the correlation was 0.79.¹¹ Reproducibility of vigorous physical activities and weight training from two questionnaires were 0.52 and 0.50 respectively. Another study has reported a correlation of 0.54 between PA score obtained from a similar questionnaire and maximum oxygen uptake.¹²

Assessment of type 2 diabetes and death

We ascertained T2DM that occurred between return of the questionnaire in 1990 and January 31 in 2008. Men who reported a diagnosis of diabetes in the biennial follow-up questionnaires were sent a supplementary questionnaire to confirm the diagnosis obtaining information on symptoms, treatment, and diagnostic tests. From 1990 to 1996 the criteria from the National Diabetes Data Group was used to confirm self-reported diagnosis of T2DM and from 1998 we used the American Diabetes Association criteria. Ninety seven percent (57 of 59) of self-reported T2DM cases were confirmed by means of medical record review in a validation study in a sub-group of HPFS participants.¹⁰ We identified deaths by reports by searching the National Death Index, next of kin or from postal authorities. Death due to cardiovascular disease (CVD) was classified using International Classification of Diseases (eighth revision). The National Death Index has an estimated sensitivity of at least 98%.¹³

Assessment of covariates

Family history of T2DM, hypertension, or coronary heart disease was assessed at baseline by self-report. Smoking status and BMI were assessed at baseline and biannually thereafter. Dietary factors were assessed in 1990, 1994, 1998, 2002, and 2006 using a 131-item validated FFQ.¹⁴ Daily intake of total energy (cal/d), saturated fat to polyunsaturated fat ratio, trans fat (% of total energy), alcohol intake, coffee intake, cereal fiber (g/d), whole grains (g/d), and glycemic load were considered as covariates in the analyses. We also calculated a dietary index composed of polyunsaturated fat to saturated fat ratio, trans fat (inverted), cereal fiber, whole grains, and glycemic load (inverted) by standardizing and summarizing the respective continuously scaled dietary variables.¹⁵

Statistical analysis

Person-time at risk was calculated from the return of the 1990 questionnaire until January 31 2008, death, loss to follow-up, or whichever occurred first. Relative risks (RRs) of T2DM by categories of weight training and aerobic exercise were estimated using time dependent cox proportional-hazard regression. To control for calendar time and age the analyses were stratified jointly by age (in months) at start of follow-up and the year of questionnaire return. We calculated cumulative averages of weight training and aerobic PA from baseline (1990) to censoring time to minimize measurement error and to characterize long term exposure status. In multivariable analysis we additionally adjusted for aerobic exercise, other PA, TV viewing, alcohol intake, coffee intake, smoking, ethnicity, family history of diabetes, and the dietary variables total calorie intake, saturated fat to polyunsaturated fat ratio, trans fat, cereal fiber, whole grains, and glycemic load. Tests for trend were performed by assigning the median value of each category of the exposure and treating this variable as continuous. To examine the combined association of weight training and aerobic exercise, we constructed a joint variable of weight training (4 categories) and aerobic exercise (2 categories representing adherence to current recommendations) and associated that with T2DM risk. Test for multiplicative interaction was done with the likelihood ratio test by comparing models with main effects and interaction terms and models only containing the

main effects. We did not see indications that the proportional hazard assumption was violated based on interaction test between follow-up time and weight training.

We also examined the nature of the possible dose-response relationship between weight training and T2DM by using restricted cubic spline regression with 4 knots.¹⁶ Deviation from linearity was tested using the likelihood ratio test by comparing models with cubic spline terms and models only containing the linear term.

We performed several sensitivity analyses to assess the robustness of the results. Firstly, we used the simple update- and the baseline information respectively on weight training as an alternative for the cumulative average. Secondly, we performed an analysis using a 4-year lag in exposure classification to assess the possibility of reverse causality. Thirdly, we included confounding variables assessed on the continuous scale in this form in the models to address the possibility of residual confounding. Finally, we repeated the analysis with death from all causes treated as a competing risk according to the method of Fine and Gray.¹⁷

All analyses were conducted in the Statistical Analysis Systems 8 software package, version 9.2 (SAS Institute, Inc., Cary, North Carolina).

Results

During 508,332 person years of follow-up (18 years), we documented 2,278 new cases of T2DM. Table 1 shows the baseline characteristics of the study population by levels of weight training per week. Fourteen percent of men reported weight training at baseline. Whereas the age adjusted percentage that engaged in weight training increased with time to 29% in 2006, the average time spent weight training among these individuals appeared stable over time (Figure 1). Men who reported weight training 150 min/week at baseline performed more aerobic exercise, viewed less TV, drank less alcohol, were less likely to smoke, and had a healthier dietary intake profile (except for glycemic load) compared to men reporting no weight training.

Table 2 shows the association of weight training and aerobic exercise with the risk of T2DM. In multivariable adjusted analysis including aerobic exercise men performing weight training 1–59, 60–149, and 150 min/week had RRs of 0.88, 0.75, and 0.66 lower risk of T2DM ($p < 0.001$ for trend), respectively, compared to men reporting no weight training. The RR for T2DM for men performing 1–59, 60–149, and 150 min/week of aerobic exercise respectively compared to men reporting no aerobic exercise was 0.93, 0.69, and 0.48 ($p < 0.001$ for trend) in multivariable adjusted analysis. When using the baseline information only or the simple updated information on weight training (instead of the cumulatively updated) results modestly attenuated (baseline: multivariable adjusted RR=0.67 (95% CI 0.51–0.88), simple updated: multivariable adjusted RR=0.75 (95% CI 0.60–0.94) for the highest categories of weight training). Using a 4 year lag in exposure classification strengthened the association (multivariable adjusted RR=0.50 (95% CI 0.33–0.76) for the highest category of weight training). To assess the possibility of residual confounding, we included covariates as continuous variables where possible, but this did not materially change the results. To further address the possibility that the association of weight training with risk of T2DM was due to confounding by aerobic exercise, we restricted the analysis to men who reported no aerobic exercise. This analysis showed that any weight training was associated with 48% (95% CI 1–72) lower risk compared to no weight training in multivariable adjusted analysis. In a secondary analysis, we also analyzed if weight training was associated with mortality from CVD ($n=1,901$ deaths) and all-causes ($n=6,251$ deaths). The age-adjusted RRs across categories of weight training were 0.76, 0.79, and 0.78

($p=0.009$ for trend) for CVD mortality and 0.75, 0.82, and 0.89 ($p=0.002$ for trend) for all-cause mortality. After multivariable adjustment including aerobic exercise, the corresponding RRs were 0.90, 1.00, and 0.98 ($p=0.82$ for trend) for CVD mortality and 0.88, 1.04, and 1.11 ($p=0.38$ for trend) for all-cause mortality. Treating death from all causes as a competing risk gave similar results to the standard cox model in the analysis with T2DM as outcome.

Adjusting for BMI moderately attenuated the associations for both weight training (multivariable adjusted RR=0.71 (95% CI 0.49–1.00) for the highest category) and aerobic exercise (multivariable adjusted RR=0.61 (95% CI 0.53–0.70) for the highest category) with T2DM risk. A sub-sample of the participants also had information on waist circumference in 1987 and 1996 (total of 413,890 person-years and 1,850 cases). Using this to assess mediation by adiposity attenuated the association of weight training and aerobic exercise to a larger extent (weight training RR=0.76 (95% CI 0.51–1.14) and aerobic exercise RR=0.62 (95% CI 0.53–0.73) for the highest categories, although the trend across categories were still present for both exercise types ($p<0.05$ for trend).

Results from the multivariable adjusted restricted cubic spline regression showed that the risk of T2DM decreased linearly with increasing time spent weight training ($p=0.59$ for non-linear response) (Figure 2). For each 60 min of weight training per week the risk of T2DM decreased by 13 percent (95% CI 6 – 19, $p<0.001$). For aerobic exercise the relationship clearly appeared non-linear with the strongest association at the lower level of aerobic exercise ($p<0.001$ for non-linear response) (eFigure).

We then examined the association of weight training and aerobic exercise stratified by age (<65, 65 years), BMI (<30, 30 kg/m²), family history of T2DM (yes, no), and dietary index score (below and above the median) (Table 3 and eTable). The association of weight training with T2DM were stronger among men below 65 years of age ($p<0.001$ for multiplicative interaction). There was also evidence that the association was stronger among men with no family history of T2DM ($p=0.04$ for multiplicative interaction). This was less apparent for aerobic exercise where associations were fairly similar across these strata (eTable).

Finally we examined the joint association of weight training and aerobic exercise with the risk of T2DM (Figure 3). Men who adhered to the current recommendations on aerobic exercise (at least 150 min/week) and engaged in weight training of at least 150 min/week had the greatest reduction in T2DM risk (RR=0.41, 95% CI 0.27–0.61), $p=0.26$ for multiplicative interaction.

Comment

In this large prospective cohort study with biannual follow-up over 18 years, men who engaged in weight training had a reduced risk of T2DM. The association was independent of aerobic exercise, and even a modest amount of time engaged in weight training appeared to be beneficial. The risk reduction associated with weight training was comparable in magnitude to that of aerobic exercise, with risk reductions of about 35% and 50% among men performing at least 150 min/week of either weight training or aerobic exercise respectively. Our results support that weight training serves as an important alternative for individuals having difficulty in adhering to aerobic exercise, but the combination of weight training with aerobic exercise conferred even a greater benefit.

Our findings are in agreement with those obtained from a recent meta-analysis of randomized controlled trials showing that resistance training can improve glycemic control among individuals with T2DM.⁶ However, no previous studies have examined the

association of weight training with the risk of T2DM. A number of cross sectional studies have shown that weight training, muscle strength, or muscle mass is associated with greater insulin sensitivity or pre-diabetes.¹⁸⁻²¹ In addition, two prospective cohort studies reported that greater muscle strength was associated with a lower risk of incident metabolic syndrome, although association was attenuated with adjustment for aerobic fitness in both reports.^{22,23} Finally, in a previous study from HPFS we have reported an inverse association of weight training with the risk of coronary heart disease independent of other physical activities.²⁴ Further studies are needed to examine the associations between weight training and other outcomes, including total and cause-specific mortality.

The two largest trials performed on resistance training among individuals with T2DM showed that the combination of aerobic exercise and resistance training conferred further benefit for glycemic control among individuals with T2DM than either type of exercise alone.^{25,26} We observed that combining aerobic exercise and weight training was associated with the largest reduction in the risk of T2DM. While we observed that the time spent engaged in weight training provided a fairly comparable reduction in risk compared to the time spent in aerobic exercise, it is unclear if the total energy expenditure plays the same role for the two types of exercise. Because the anaerobic energy expenditure contribution during weight training can be substantial, the energy requirements for weight training may be grossly underestimated when comparing it to aerobic exercise using MET values. Furthermore, we did not obtain specific information on the type and intensity of weight training. Thus, it is uncertain if the altered daily total energy expenditure from engaging in aerobic exercise is comparable to those from weight training in our study.

Although many of the acute and chronic physiological responses induced by resistance training and aerobic exercise are similar, there are also clear distinct effects of each exercise type.²⁷ On the cellular level engagement in aerobic exercise increases mitochondrial density and oxidative enzyme activity thereby facilitating improved ability of fatty acid oxidation, whereas resistance training increases the glycolytic capacity and promotes type-II muscle fiber abundance and growth which enhances the capacity of glucose utilization.²⁸ In turn, aerobic exercise leads to greater improvements in aerobic fitness while resistance training favors increases lean body mass and muscle strength.^{29,30} Beyond improving glycemic control, both exercise types have been shown to reduce adiposity and improve blood pressure- and lipid levels.³¹⁻³⁴

We did not observe a strong attenuation of the association with weight training after additional adjustment for BMI. This may be attributable to weight training being able to increase lean mass and reduce fat mass without a major change in body weight, as previously indicated in trials among individuals with T2DM.^{25,26} However, using waist circumference indicated that part of the beneficial effect of weight training was mediated by abdominal adiposity. In our previous analysis, weight training was associated with a smaller increase in waist circumference over time in men.³⁵

We found that the association of weight training with T2DM risk was attenuated among men 65 years of age and above and among men with a family history of T2DM. The attenuation of association in these subgroups may be attributed to power. An alternative explanation could be that the intensity of weight training is decreased at old age. However, we do not have data to test this hypothesis. The possible weakened relationship between weight training and T2DM risk among men with a positive family history deserves more attention in future studies.

The strengths of this study include the large sample size, long follow-up time, and the biannual assessment of exposures and most confounders including important dietary factors.

We were also able to show that associations were robust to a number of sensitivity analyses including an analysis using a 4-year lag in exposure classification. Limitations include that the study only comprised men who were working health professionals and mostly white. The findings may therefore not be generalizable to women and other ethnic or racial groups of men. Furthermore, we were not able to explore the importance of type and intensity of weight training as we only obtained information on weekly non-specific weight training. Finally, there is a possibility of residual and unknown confounding. Because we observed risk reduction with any weight training among individuals reporting no aerobic exercise it is unlikely that the association of weight training can be explained by residual confounding by aerobic exercise.

In conclusion, this prospective cohort study showed that weight training was associated with a reduced risk of T2DM in a dose response manner independent of aerobic exercise level. The magnitude of risk reduction associated with weight training was close to that of aerobic exercise. Our results support that weight training is a valuable alternative for individuals having difficulty adhering to aerobic exercise and adding weight training to aerobic exercise appears to give further protection from T2DM. Further research should examine the influence of duration, type and intensity of weight training on T2DM risk in greater detail.

Figure 1. Participation in weight training over time (1990 – 2006)

Data are age adjusted percentage of men engaged in weight training and mean minutes/week of weight training among men engaged in weight training across study year.

Figure 2. Dose response relationship between weight training (min/week) and risk of type 2 diabetes

Dotted lines are 95% CI for the trend obtained from restricted cubic spline regression (4 knots). The model included the following covariates: age (months), aerobic exercise (0, 1–59, 60–149, 150 min/week), other physical activity of at least moderate intensity (quintiles), TV viewing (quintiles), smoking (never, past, or current with cigarette use of 1–14, 15–24, 25 per day), alcohol consumption (0, 1–5, 6–10, 11–15, >15 g/d), coffee intake (0, <1, 1–3, 3–5, >5 cups/day), race (white, non-white), family history of diabetes, intake of total energy, trans fat, polyunsaturated fat to saturated fat ratio, cereal fiber, wholegrain, and glycemic load (all dietary factors in quintiles). The analysis was truncated to men reporting 420 min/week. $P=0.59$ for non-linear relationship.

Figure 3. Joint association of weight training and aerobic exercise with the risk of type 2 diabetes
 Data are estimates of RR with 95% CI from multivariate cox regression models adjusted for age (months), other physical activity of at least moderate intensity (quintiles), TV viewing (quintiles), smoking (never, past, or current with cigarette use of 1–14, 15–24, ≥25 per day), alcohol consumption (0, 1–5, 6–10, 11–15, >15 g/d), coffee intake (0, <1, 1–3, 3–5, >5 cups/day), race (white, non-white), family history of diabetes, intake of total energy, trans fat, polyunsaturated fat to saturated fat ratio, cereal fiber, wholegrain, and glycemic load (all dietary factors in quintiles). Adherence to the recommendations on aerobic exercise is at least 150 min/week.

Table 1

Age-adjusted baseline (1990) characteristics of the study population by levels of weight training per week.

	Minutes per week of weight training			
	None	1 – 59	60 – 149	150
No	26,439	2,068	2,078	1,417
BMI (kg/m ²)	25.6(3.3)	25.1(2.7)	24.9(2.6)	24.9(2.7)
Aerobic exercise* (h/w)	3.2(5.1)	4.4(5.1)	5.5(5.4)	6.9(14.2)
Other physical activity (MET-h/w)**	9.1(22.3)	5.5(13.5)	6.1(14.6)	8.4(16.8)
TV viewing (h/w)	10.3(8.4)	9.4(8.0)	9.5(7.7)	9.6(7.7)
Alcohol intake (g/d)	10.2(14.5)	10.6(14.1)	10.8(13.1)	9.8(12.5)
Coffee intake (cups/d)	1.3(1.6)	1.1(1.5)	1.2(1.6)	1.1(1.5)
P:S ratio	0.6(0.2)	0.6(0.2)	0.6(0.2)	0.7(0.2)
Transfat (% of total energy)	1.5(0.6)	1.4(0.6)	1.4(0.6)	1.3(0.6)
Cereal fiber (g/d)	6.3(4.3)	7.1(4.6)	7.1(4.7)	7.2(5.0)
Whole grains (g/d)	24.6(20.3)	28.9(22.7)	29.2(21.6)	31.8(29.2)
Glycemic load	125(47)	130(48)	129(47)	132(49)
Total energy intake (kcal/d)	1928(600)	1943(602)	1937(596)	1942(598)
Dietary index z-score (SD)***	-0.1(2.5)	0.5(2.6)	0.7(2.6)	0.9(3.0)
Current smoking, %	8	4	4	5
Race, % white	96	94	97	96
Family history of diabetes, %	15	15	15	14

Values are means(SD) or percentages and are standardized to the age distribution of the study population. P:S ratio, polyunsaturated fat to saturated fat ratio; MET, metabolic equivalent task.

* Aerobic exercise consists of walking with brisk pace, jogging, running, bicycling, swimming, tennis, squash, and calisthenics/rowing.

** Other physical activity consists of heavy outdoor work and stair climbing.

*** Dietary index is the sum of standardized saturated fat to polyunsaturated fat ratio, trans fat (inverted), cereal fiber, whole grains, and glycemic load (inverted).

Table 2

Weight training, aerobic exercise and risk of type 2 diabetes in men from Health Professional Follow-up Study (1990–2008).
