Metalenses at visible wavelengths: Diffraction-limited focusing and subwavelength resolution imaging

Mohammadreza Khorasaninejad,1 Wei Ting Chen,1 Robert C. Devlin,1 Jaewon Oh,1,2 Alexander Y. Zhu,1 Federico Capasso1†

Subwavelength resolution imaging requires high numerical aperture (NA) lenses, which are bulky and expensive. Metasurfaces allow the miniaturization of conventional refractive optics into planar structures. We show that high-aspect-ratio titanium dioxide metasurfaces can be fabricated and designed as metalenses with NA = 0.8. Diffraction-limited focusing is demonstrated at wavelengths of 405, 532, and 660 nm with corresponding efficiencies of 86, 73, and 66%. The metalenses can resolve nanoscale features separated by subwavelength distances and provide magnification as high as 170×, with image qualities comparable to a state-of-the-art commercial objective. Our results firmly establish that metalenses can have widespread applications in optical technology by enabling versatile functionalities in a planar structure (1–30). Various optical components, ranging from lenses, holograms and gratings to polarization-selective devices, have been demonstrated using silicon-based (7–19) and plasmonic metasurfaces (3, 4, 21–27). However, the high intrinsic losses of silicon and plasmonic materials in the visible range (400 to 700 nm) have prevented the realization of highly efficient metasurfaces in this region. Although this challenge can be partially overcome by using dielectric materials with a transparency window in the visible spectrum (e.g., GaP, SiN, and TiO2), achieving full control over the phase of light requires precise, high-aspect-ratio nanostructures, which are in turn restricted by available nanofabrication methods. Recently, we have developed an approach based on titanium dioxide (TiO2) (31) prepared by atomic layer deposition (ALD), which enables fabrication of high-aspect-ratio metasurfaces that are lossless in the visible spectrum. Here, we demonstrate highly efficient metalenses at visible wavelengths (λ = 405, 532, and 660 nm) with efficiencies as high as 86%. They have high numerical apertures (NA) of 0.8 and are capable of focusing light into diffraction-limited spots. At their respective design wavelengths, these focal spots are smaller by a factor of ~1.5 than those from a commercially available, high-NA objective (100× Nikon CFI60; NA = 0.8). Imaging using these metalenses shows that they can yield subwavelength resolution, with image qualities comparable to that obtained by the commercial objective.

**Planar lens design and fabrication**

Typical high-NA objectives consist of precision-engineered compound lenses which make them bulky and expensive, limiting their applications and hindering their integration into compact and cost-effective systems. Singlet planar lenses with high NA in the visible range are in particularly high demand due to their potential widespread applications in imaging, microscopy, and spectroscopy. Although visible planar lenses can be realized by diffractive components, high NA and efficiency are not attainable because their constituent structures are of wavelength scale, which precludes an accurate phase profile.

Figure 1A shows a schematic of a transmissive dielectric metalens. The building blocks of the metalens are high-aspect-ratio TiO2 nanofins (Fig. 1, B to E). To function like a spherical lens, the phase profile \( \psi_{\text{opt}}(x, y) \) of the metalens needs to follow (25)

\[
\psi_{\text{opt}}(x, y) = \frac{2\pi}{\lambda_0} \left( f - \sqrt{x^2 + y^2 + f^2} \right)
\]

where \( \lambda_0 \) is the design wavelength, \( x \) and \( y \) are the coordinates of each nanofin, and \( f \) is the focal length. This phase profile is imparted via rotation of each nanofin at a given coordinate \((x, y)\) by an angle \( \theta_{\text{opt}}(x, y) \) (Fig. 1E). In the case of right-handed circularly polarized incident light, these rotations yield a phase shift, \( \psi_{\text{opt}}(x, y) = 2\theta_{\text{opt}}(x, y) \), accompanied by polarization conversion to left-handed circularly polarized light (33, 34). Thus, each nanofin at \((x, y)\) is rotated by an angle

\[
\theta_{\text{opt}}(x, y) = \frac{\lambda_0}{f} \left( f - \sqrt{x^2 + y^2 + f^2} \right)
\]

To maximize the polarization conversion efficiency, the nanofins should operate as half-waveplates (21–23). This is achieved due to the birefringence arising from the asymmetric cross section of nanofins with appropriately designed height, width, and length (Fig. 1C and D). Simulations using a commercial finite difference time domain (FDTD) solver (Lumerical Inc., Vancouver) in Fig. 1F show that conversion efficiencies as high as 95% are achieved and that the metalens can be designed for a desired wavelength via tuning of nanofin parameters. The conversion efficiency is calculated as the ratio of transmitted optical power with opposite helicity to the total incident power.

Three distinct metalenses were fabricated with respective design wavelengths (\(\lambda_0\)) of 660, 532, and 405 nm. All of these metalenses have the same diameter of 240 μm and a focal length of 90 μm, yielding a NA = 0.8. The fabrication process uses electron-beam lithography to create the lens pattern in the resist (ZEP 520A). The thickness of the resist is the same as the designed nanofin height, \(H\), and ALD is subsequently used to deposit amorphous TiO2 onto the developed resist. Amorphous TiO2 is chosen because it has low surface roughness, no absorption at visible wavelengths, and a sufficiently high refractive index (~2.4). Due to the ALD process being conformal, a deposition thickness of at least \(W/2\) (where \(W\) is the nanofin width) is required to produce void-free nanofins (37). However, the deposition also leaves a TiO2 film of equal thickness on top of the resist, which is then removed by controlled blanket reactive ion etching. Finally, the remaining electron beam resist is stripped, and only high-aspect-ratio nanofins remain. Figure 1, G and H, shows optical and scanning electron microscope (SEM) images of a fabricated metalens, respectively. Additional SEM micrographs of the metalens are shown in fig. S1 (35). Because the geometrical parameters of the nanofins are defined by the resist rather than top-down etching, high-aspect-ratio nanofins with ~90° vertical sidewalls are obtained. It is important to note that achieving these atomically smooth sidewalls is very challenging with a conventional top-down approach (e.g., lithography followed by dry etching), because inevitable lateral etching results in surface roughness and tapered/conical nanostructures.

**Characterizing metalens performance**

The metalens’ focal spot profiles and efficiencies were measured using the experimental setup shown in fig. S2. Figure 2A shows a highly symmetric focal spot that is obtained for the metalens at its design wavelength \(\lambda_0 = 660\) nm. The vertical cut of the focal spot is also shown in Fig. 2G with a diffraction-limited (\(\frac{1}{\text{FWHM}}\)) full-width at half-maximum (FWHM) of 450 nm. Figure 2, B and H, show the focal spot of the metalens...
though this wavelength is very close to the band
of (Fig. 2I). Alternations in Fig. 2, G to I, and Fig. 2, J to L, reveals
setup as in fig. S2 (see Fig. 2, D to F). A compar-
532, and 405 nm were measured using the same
theoretical root mean squares of the wave

designed for 405, 532, and 660 nm are 0.049,
and 0.064, respectively. These values are
the metalenses were designed at specific wavelengths,
we still observe wavelength-scale focal spots at
wavelengths away from the design. For example,
for the metalens designed at $\lambda = 532$ nm, we
measured focal spot sizes of 720 and 590 nm at
wavelengths of $\lambda = 660$ and 405 nm, respectively
(fig. S4). The broadening of the focal spots with
respect to the theoretical diffraction-limited val-
ues comes from chromatic aberration because
metasurfaces are inherently dispersive. Chromatic
aberrations in our metalens are more pronounced
than the lenses based on refractive optics, result-
ing in a wavelength-dependent focal length (fig.
SSA). This is generally not an issue for laser-
related imaging, microscopy, and spectroscopy
because monochromatic sources with narrow
linewidths are used. For example, in Raman
microscopes/spectrometers, a 532-nm laser with
a linewidth of a few picometers is common. In
this case, the linewidth-induced broadening of the
focal spot size and change in focal length is
negligible.
We also measured the focusing efficiency of
the metalenses. As shown in Fig. 3A, the metalens
designed at $\lambda = 660$ nm has a focusing efficiency
of 66%, which remains above 50% in most of the
waveguide range. Figure 3A also shows the measured
focusing efficiency of the metalens designed at
$\lambda = 532$ nm. This metalens has a focusing effi-
ciency of 73% at its design wavelength. In addi-
tion, we measured the beam intensity profile of
this metalens in the x-z cross section within a
40-$\mu$m span around the focal point (Fig. 3B).
Details of this measurement are discussed in the
supplementary materials (35) (see fig. S2 and
materials and methods). The negligible back-
ground signal not only demonstrates excellent
phase realization, where the beam converges to
a diffraction-limited spot, but also shows the
high conversion efficiency of each nanofin. For
the metalens designed at the wavelength of
405 nm, a measured focusing efficiency of 86% is
achieved. The latter measurement was done
using a diode laser (Ondax Inc., Monrovia, CA)
because the shortest wavelength that our tunable
laser (SuperK Varia) can provide was $\sim$470 nm.
All of the efficiency measurements were performed
using right circularly polarized incident light.
However, the polarization sensitivity of the de-
sign can be overcome by implementing the phase
profile using circular cross section nanopillars in
designed at the wavelength of 532 nm and its cor-
responding vertical cut. Moreover, this metalens
design can be extended to the shorter wavelength
region of the visible range, which is of great
interest in many areas of optics, such as lithography
and photoluminescence spectroscopy. Figure 2C
depicts the intensity profile of the focal spot from
the metalens designed at the wavelength $\lambda =
405$ nm with a FWHM of 280 nm (Fig. 2D).
Although this wavelength is very close to the band
gap of TiO$_2$, $\lambda_g = 360$ nm, the absorption loss is
still negligible (37).
To compare the performance of our metalenses
with a commercially available lens, we selected a
state-of-the-art Nikon objective. This objective
has the same NA as our metalenses (0.8) and is
designed for visible light. Focal spot intensity
profiles of the objective at wavelengths of 660,
532, and 405 nm were measured using the same
setup as in fig. S2 (see Fig. 2, D to F). A compari-
on of the corresponding focal spot cross
sections in Fig. 2, G to I, and Fig. 2, J to L, reveals
that the metalenses provide smaller (~1.5 times)
and more symmetric focal spots. This can be un-
derstood because conventional high-NA objec-
tives are designed to image under broadband
illumination. That is, wavefront aberrations need
to be corrected for multiple wavelengths over a
range of angles of incidence to meet industry
standards for the required field of view. This is
typically implemented by cascading a series of
precisely aligned compound lenses. Fabrication
imperfections in each individual optical lens and
residual aberration errors, particularly spherical
aberration, result in a focal spot size larger
than theoretical predictions (36). In contrast,
our metalens is designed to have a phase profile
free of spherical aberration for normally incident
light, which results in a diffraction-limited spot
at a specific design wavelength (37). For example,
the theoretical root mean squares of the wave
aberration function (WAFRMS) for the metalenses
designed for 405, 532, and 660 nm are 0.049$\alpha$,
0.060$\lambda$, and 0.064$\lambda$, respectively. These values are
very close to the condition for a perfect spherical
wavefront (37). We also calculated the Strehl ra-
tio from the measured beam profiles for the
three metalenses at their design wavelengths
and found that they are close to 0.8 (see mate-
rials and methods and fig. S3), consistent with the
observed diffraction-limited focusing. In addi-
tion, due to the use of the geometric phase, the
phase profile of the metalens is only dependent
on the rotation of the nanofins. This is controlled
with very high precision, as is characteristic of
electron-beam lithography. Alternatively, other
high-throughput lithography methods such as
deep-ultraviolet (UV) can provide similar fabri-
cation accuracy.

It is important to note that although the
metalenses were designed at specific wavelengths,
we observe wavelength-scale focal spots at
wavelengths away from the design. For example,
for the metalens designed at $\lambda = 532$ nm, we
measured focal spot sizes of 720 and 590 nm at
wavelengths of $\lambda = 660$ and 405 nm, respectively
(fig. S4). The broadening of the focal spots with
respect to the theoretical diffraction-limited val-
ues comes from chromatic aberration because
metasurfaces are inherently dispersive. Chromatic
aberrations in our metalens are more pronounced
than the lenses based on refractive optics, result-
ing in a wavelength-dependent focal length (fig.
SSA). This is generally not an issue for laser-
related imaging, microscopy, and spectroscopy
because monochromatic sources with narrow
linewidths are used. For example, in Raman
microscopes/spectrometers, a 532-nm laser with
a linewidth of a few picometers is common. In
this case, the linewidth-induced broadening of the
focal spot size and change in focal length is
negligible.
We also measured the focusing efficiency of
the metalenses. As shown in Fig. 3A, the metalens
designed at $\lambda = 660$ nm has a focusing efficiency
of 66%, which remains above 50% in most of the
waveguide range. Figure 3A also shows the measured
focusing efficiency of the metalens designed at
$\lambda = 532$ nm. This metalens has a focusing effi-
ciency of 73% at its design wavelength. In addi-
tion, we measured the beam intensity profile of
this metalens in the x-z cross section within a
40-$\mu$m span around the focal point (Fig. 3B).
Details of this measurement are discussed in the
supplementary materials (35) (see fig. S2 and
materials and methods). The negligible back-
ground signal not only demonstrates excellent
phase realization, where the beam converges to
a diffraction-limited spot, but also shows the
high conversion efficiency of each nanofin. For
the metalens designed at the wavelength of
405 nm, a measured focusing efficiency of 86% is
achieved. The latter measurement was done
using a diode laser (Ondax Inc., Monrovia, CA)
because the shortest wavelength that our tunable
laser (SuperK Varia) can provide was $\sim$470 nm.
All of the efficiency measurements were performed
using right circularly polarized incident light.
However, the polarization sensitivity of the de-
sign can be overcome by implementing the phase
profile using circular cross section nanopillars in

dation accuracy. (G) Optical image of the metalens designed at the wavelength of 660 nm. Scale bar, 40 $\mu$m. (H) SEM micrograph of the fabricated metalens. Scale bar, 300 nm.](https://www.sciencemag.org/content/sci/352/6290/1191/F1.large.jpg)
which the phase is controlled via changing their diameters.

**Imaging demonstration**

To demonstrate the use of our metalens for practical imaging, we fabricated a metalens with diameter \( D = 2 \) mm and focal length \( f = 0.725 \) mm giving NA = 0.8. First, we characterized the imaging resolution using the 1951 United States Air Force (USAF) resolution test chart (Thorlabs Inc., Jessup, MD) as the target object. The measurement configuration is shown in fig. S6. Figure 4A shows the image formed by the metalens. The light source was a tunable laser (SuperK Varia) set at 530 nm with a bandwidth of 5 nm. Because the resulting image was larger than our charge-coupled device (CCD) camera, we projected the image onto a translucent screen and took its
photo with a Canon digital single-lens reflex (DSLR) camera. The smallest features in this object are lines with widths of 2.2 μm and center-to-center distances of 4.4 μm (the bottom element in the highlighted region). A similar quality is achieved at wavelengths covering the visible spectrum (fig. S7). Images of the smallest features were taken with a CCD camera shown in Fig. 4, B to E, at wavelengths of 480, 530, 590, and 620 nm, respectively. It is clear that the metalens can resolve these micrometer-sized lines. We repeated a similar experiment using a Siemens star target and showed that all features can be resolved over the whole visible range (figs. S8 and S9). As mentioned previously, the focal length of the metalens varies as the wavelength changes, resulting in different levels of magnification (fig. S8B). In our experimental setup, we used the metalens together with a tube lens (f = 100 mm), giving a magnification of 138× (100/0.725) at 530 nm. For wavelengths of 480, 590, and 620 nm, magnifications of 124×, 152×, and 167× are obtained, respectively, by comparing the ratio of the image sizes formed on the camera to the known physical size of the USAF test object.

To characterize the effects of chromatic aberration, we imaged the same object at 530 nm without changing the distance between the metalens and the object, while varying the bandwidth of the source from 10 to 100 nm (the limit of our tunable laser). These results are shown in Fig. 4, F to I. Although the quality of the image slightly degrades from increasing the bandwidth, the smallest features are still resolvable even at the maximum bandwidth of 100 nm. Finally, for comparison of the imaging quality to that of a conventional objective, we fabricated an H-shaped object composed of arrays of holes with gaps of ~800 nm using a focused ion beam (FIB). An SEM micrograph of the object is shown in Fig. 4 J. The image formed by the metalens (Fig. 4 K) has comparable quality to the one formed by the 100× Nikon objective (Fig. 4 L) with the same NA = 0.8. The change in the image sizes comes from the difference in the magnification of the imaging systems. We also tested the resolution limit of our metalens: Four holes with subwavelength gap sizes of ~450 nm can be well resolved (Fig. 4 M). This value agrees with the measured modulation transfer function of our metalens (supplementary materials and fig. S10).

**Concluding remarks**

The demonstrated visible-range metalenses, using TiOx with NA = 0.8 and efficiencies as high as 86%, show that they are able to provide diffraction-limited focal spots at arbitrary design wavelengths, which make them ideal devices for use in optical lithography, laser-based microscopy, and spectroscopy. Providing a magnification as high as 170× and capable of resolving structures with subwavelength spacing, the compact configuration of our metalenses can enable portable/handheld instruments for many applications. Although our metalenses are subject to chromatic aberrations, the latter can be corrected with approaches such as dispersive phase compensation demonstrated

Structure and torsional dynamics of the water octamer from THz laser spectroscopy near 215 μm

William T. S. Cole,1,2* James D. Farrell,2* David J. Wales,2† Richard J. Saykally†

Clusters of eight water molecules play an important role in theoretical analysis of aqueous structure and dynamics but have proven to be challenging experimental targets. Here we report the high-resolution spectroscopic characterization of the water octamer. Terahertz (THz) vibration-rotation-tunneling (VRTX) spectroscopy resolved 99 transitions with 1 part per million precision in a narrow range near 46.5 wave numbers, which were assigned to the \( h_{16} \) octamer via detailed isotope dilution experiments. Fitting to a semi-rigid symmetric top model supports predictions of two coexisting cuboidal structures and provides precise values for the changes in their rotational constants. Comparison with theory and previous spectroscopic data provides a characterization of the two structures and the observed torsional vibration and supports the prediction that the \( D_{2d} \) symmetry structure is lower in energy than the \( S_4 \) isomer.

Spectroscopic study of water clusters provides accurate benchmarks for detailed characterization of the complex pairwise and many-body forces that operate in bulk water phases, which have proven difficult to adequately capture through bulk experiments or theory (1–4). The need to accomplish this goal is underscored by recurring controversies surrounding the fundamental intermolecular structure and dynamics of water (2, 5, 6). Clusters ranging from dimer through heptamer, as well as nonamer and decamer (7), have been studied in detail by high-precision microwave and terahertz spectroscopy, but the octamer has proven elusive (1, 2, 8–10). Whereas the most stable structures of smaller clusters evolve with size from quasiplanar rings to three-dimensional (3D) cages, the octamer represents the transition to cuboidal (8) structures formed by stacking quasiplanar four- and five-membered rings, a dominant motif in larger systems.

Accordingly, the water octamer has become a benchmark for theory, starting with the early work of Stillinger and David (11), Brink and Glasser (12), and Allen and Jordon (13). Many groups have since investigated the structures, melting transitions, and hydrogen bond (HB) rearrangement dynamics of the octamer cluster (14–30). However, experimental characterization has been very challenging, with only a few successful mid-infrared (IR) spectroscopy (31–34) and crystallographic studies (35–37). The mid-IR results are particularly interesting, revealing two nonpolar low-energy structures (Fig. 1) formed by stacking of homodromic tetramer rings with the in-plane HBs directed in either the same (\( S_4 \) symmetry) or opposite (\( D_{2d} \) symmetry) senses. Both structures possess two distinct monomer environments: single HB donor and double HB donor, with the latter responsible for the association between the two tetramer rings. These structures have subsequently been refined by theory, with several groups calculating the ground state energy difference between the \( S_4 \) and the \( D_{2d} \) structures to be less than 0.1 kJ/mol (14–17, 37). Given such a small energy difference, both structures should be present even in very low temperature environments, e.g., supersonic beams.

Here we present the results of a study of the water \( h_{16} \)-octamer by terahertz vibration-rotation-tunneling (VRTX) spectroscopy, involving the measurement of a very low frequency torsional vibration in both low-lying isomers. Nearly 100 individual vibration-rotation transitions have been measured to parts per million (ppm) accuracy and fitted to a standard semi-rigid symmetric rotor model, producing rotational constants, which, when combined with theoretical values, characterize the structures and vibrational distortions of the cluster. The results are in good agreement with recent theoretical predictions of the HB rearrangement tunneling rates (8) and cluster structures.

In an earlier study, Richardson et al. presented VRT spectra comprising 99 weak transitions measured near 1.4 THz and assigned to the \( h_{16} \)-water octamer cluster on the basis of detailed isotopic dilution studies (8). Spectral assignment was not possible at that time. In the same study, application of the ring polymer perturbative instanton method predicted the HB rearrangement tunneling rates for the \( h_{16} \)-octamer. Those results indicated that even for the most energetically accessible rearrangement, the magnitude of the tunneling
Editor's Summary

Multifunction planar optics

Specially designed two-dimensional (2D) arrays of nanometer-scale metallic antennas, or metasurfaces, may allow bulky optical components to be shrunk down to a planar device structure. Khorasaninejad et al. show that arrays of nanoscale fins of TiO can function as high-end optical lenses. At just a fraction of the size of optical objectives, such planar devices could turn your phone camera or your contact lens into a compound microscope. Maguid et al. interleaved sparse 2D arrays of metal antennas to get multifunctional behavior from the one planar device structure (see the Perspective by Litchinitser). The enhanced functionality of such designed metasurfaces could be used in sensing applications or to increase the communication capacity of nanophotonic networks.

Science, this issue pp. 1190 and 1202; see also p. 1177
