X - 2 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW
Abstract. Ice flow over a Snowball ocean was shown in recent years to
be capable of very effectively homogenizing ice thickness globally. Previous
studies all used local or one-dimensional global (latitude-only) models, for-

sciences and school of engineering and applied sciences, Cambridge, MA, USA.

mulated in a way that is difficult to extend to two-dimensional global con-6 figuration. This paper uses a two-dimensional global ice flow model to study 7 the effects of continental constriction on ice flow and ice thickness in a Snowball-8 Earth scenario using reconstructed Neoproterozoic land-mass configuration. 9 Numerical simulations and scaling arguments are used to show that various 10 configurations of continents and marginal seas which are not represented by 11 one dimensional models lead to large ice thickness variations, including nar-12 row areas between sub-continents and marginal seas whose entrance is con-13 stricted. This study ignores many known important factors such as thermo-14 dynamic, optical effects, dust and dust transport, and is therefore meant as 15 a process study focusing on one specific effect, rather than a realistic sim-16 ulation of Neoproterozoic ice thickness. The model formulation developed 17 here generalizes and extends previous results in several ways, including the 18 introduction of corrections due to spherical coordinates and lateral geom-19 etry. This study is therefore a step toward coupling Snowball ice flow mod-20 els to general circulation ocean and atmospheric models and allowing a more 21 quantitative simulation of Neoproterozoic Snowball ice thickness. 22

1. Introduction

Between 750 and 580 million years (Myr) ago, during the Neoproterozoic era, Earth experienced multiple ice ages, some of which deposited glaciogenic sediments in equatorial seas indicating possible global ice cover [*Harland*, 1964; *Kirschvink*, 1992; *Hoffman et al.*, 1998]. Understanding these events is an interesting challenge to our knowledge of climate dynamics. Some of the related issues and controversies are described in a recent review by *Pierrehumbert et al.* [2011].

The flow of ice over the ocean in a Snowball Earth scenario has received significant attention over the past few years. It was demonstrated by *Goodman and Pierrehumbert* [2003], that ice flow effectively homogenizes ice thickness in a Snowball Earth scenario. Ice thickness, in turn, plays a potentially important role in the question of the survival of photosynthetic life during a Snowball event [*Hoffman and Schrag*, 2002; *Pollard and Kasting*, 2005; *McKay*, 2000; *Campbell et al.*, 2011], and an ice cover of more than tens of meters could be too thick for photosynthesis [*McKay*, 2000].

Related work has so far dealt with the consequences of ice flow [Goodman and Pier*rehumbert*, 2003], with the optical properties of ice [McKay, 2000; Warren et al., 2002], with the effect of different optical properties of frozen sea water vs. accumulated snow [Pollard and Kasting, 2005, 2006; Warren and Brandt, 2006; Goodman, 2006], with the role of dynamic vs. thermodynamic sea ice [Lewis et al., 2007], and with dust accumulation over the Snowball ice cover [Abbot and Pierrehumbert, 2010; Le Hir et al., 2010] and dust transport [Li and Pierrehumbert, 2011]. ⁴³ Warren et al. [2002] and Pollard and Kasting [2005] suggested that constricted marginal ⁴⁴ seas may lead to large ice thickness variations because the ice flow into the sea is limited ⁴⁵ by friction with the side walls of the leading passage, and may not be able to balance ⁴⁶ the ablation/ melting within the sea. In a recent work, especially relevant to the work ⁴⁷ presented here, *Campbell et al.* [2011] considered the invasion of an elongated rectangular-⁴⁸ shaped marginal sea by ice flow, under the influence of friction by the side walls of the ⁴⁹ sea. They derived a formula for the invasion length based on an analytic solution of *Nye* ⁵⁰ [1965].

All calculations of Snowball ice flow that have so far been carried out used either onedimensional (in latitude) global models, or an idealized local rectangular marginal sea. Furthermore, the formulation of global one dimensional (latitude only) models was based on a formula for ice shelf deformation rate [*Weertman*, 1957], which, unfortunately, cannot be extended to two dimensions (longitude and latitude).

This paper has two main objectives. The first objective is to study the ice flow on a 56 sphere in the presence of continents, and the possibility of large ice thickness variations 57 developing due to the existence of constricted seas. We show numerical solutions based 58 on reconstructed continental configuration for the Neoproterozoic, as well as scaling re-59 lationships for ice thickness variations. We derive scaling relationships for both a global 60 continent-free ocean, and for a constricted sea with a channel connecting it to the ocean. 61 Our second objective is to formulate the ice flow problem on a sphere, including both 62 horizontal dimensions. To do this, we introduce several novel aspects and introduce 63 physical processes and mathematical terms so far neglected in the Snowball literature. 64 Importantly, we derive the equations directly from the Stokes equations. This allows the 65

formulation of a two-dimensional horizontal flow problem, which is not possible using the approach of pioneering studies of Snowball ice flow [*Goodman and Pierrehumbert*, 2003; *Pollard and Kasting*, 2005] because they started from the ice shelf strain rate formula of *Weertman* [1957]. In particular, we employ the ice shelf momentum budget of *Morland* [1987] [see also *MacAyeal and Barcilon*, 1988; *MacAyeal*, 1989, 1997], as well as spherical coordinates, and show that both of these factors lead to additional terms even in a onedimensional formulation.

Many factors are now known to play a role in setting ice thickness on a Snowball Earth, 73 and some of them (ice optical properties, different ice sources, dust and dust transport) 74 have been studied in the papers mentioned above. In this paper, we focus on the effects 75 of the ice flow and its interaction with continental configuration, and ignore, for now, 76 all other feedbacks. This has the advantage of allowing us to isolate and carefully study 77 the related flow dynamics, but necessarily makes this study idealized and over-simplified. 78 We feel this is a useful approach, yet emphasize that as a result we do not expect the 79 numerical values of the ice thickness calculated here to be a reliable quantitative predictor 80 of Snowball ice thickness. This work should therefore be viewed as a process study rather 81 than an attempt at a realistic Snowball simulation. In particular, we assume that the 82 ocean is entirely covered with thick ice [termed "sea glaciers" by Warren et al., 2002], 83 and our results cannot be used to confirm or deny the possibility of ice free conditions or 84 thin ice developing in the tropics as suggested in some previous works [e.g., Chandler and 85 Sohl, 2000; Hyde et al., 2000; Pollard and Kasting, 2005; Liu and Peltier, 2010; Abbot 86 et al., 2011b]. 87

In the following sections we present an outline derivation of the model equations (section 2). These equations are a simple extension to spherical coordinates of well-known ice shelf equations used for a long time in glaciology [*Morland*, 1987; *MacAyeal*, 1997]. We then show the model results (section 3), derive scaling laws for ice thickness in an axisymmetric global case without continents and in the case of a constricted sea (section 4), and conclude in section 5. The appendices present a detailed derivation of the model equations.

2. The model: two-dimensional ice-shelf flow on a sphere

We provide an outline of the model derivation here, with full details given in appendix A. Let the coordinates (longitude, co-latitude, vertical) be denoted by (ϕ, θ, z) and the corresponding velocities be (u, v, w). The momentum equations are,

$${}^{_{97}} \qquad \qquad 0 = -\frac{1}{r\sin\theta}\partial_{\phi}p + (\nabla\cdot\boldsymbol{\tau})\cdot\hat{\mathbf{e}}_{\phi} \tag{1}$$

98
$$0 = -\frac{1}{r}\partial_{\theta}p + (\nabla \cdot \boldsymbol{\tau}) \cdot \hat{\mathbf{e}}_{\theta}$$

$$_{\scriptscriptstyle 100}^{\scriptscriptstyle 99} \qquad \qquad 0 = -\partial_z p - g
ho_I + (
abla \cdot oldsymbol{ au}) \cdot \hat{f e}_z,$$

where r is the Earth radius taken to be constant; p is the pressure; g gravitational acceleration; ρ_I the ice density; $\boldsymbol{\tau} = \{\tau_{ij}\}$ is the stress tensor, and it is important to note that the divergence $\nabla \cdot$ of a second order tensor in curvilinear coordinates contains some metric terms in addition to those appearing in the divergence of a vector (appendix B). Unit vectors in the directions of the three coordinates are denoted $\hat{\mathbf{e}}_{\phi}$, $\hat{\mathbf{e}}_{\theta}$ and $\hat{\mathbf{e}}_z$. We use Glen's flow law [*Glen*, 1955] to relate the stress to the rate of strain $\dot{\epsilon}_{ij}$,

107
$$\tau_{ij} = A(T)^{-\frac{1}{3}} \dot{\epsilon}^{\frac{1}{3}-1} \dot{\epsilon}_{ij}$$

$$\dot{\epsilon}^2 = \dot{\epsilon}_{mn} \dot{\epsilon}_{mn}/2,$$

where T is the ice temperature and A(T) is the temperature dependence of ice viscosity, 110 which we take to be that used by *Goodman and Pierrehumbert* [2003]. We assume the 111 temperature varies linearly in depth from a prescribed surface temperature to the freezing 112 temperature at the base of the ice, which we assume constant. We use two different 113 prescribed surface temperature latitudinal profiles which we refer to as the "warm" and 114 "cold" profiles. These surface temperatures are a smooth fit to those calculated by the 115 NCAR Community Atmospheric Model assuming a surface albedo of 0.6 at high (10^5) 116 ppm) and low (100 ppm) CO_2 values [Abbot et al., 2011a]. The boundary conditions are 117 that the dot product of stress with the normal vector vanishes at the top of the ice, and is 118 equal to the hydrostatic pressure force normal to the bottom of the ice [MacAyeal, 1997], 119

(7 - p**I**)
$$\cdot \hat{\mathbf{n}}_s = 0,$$
 (2)
(7 - p**I**) $\cdot \hat{\mathbf{n}}_b = -\hat{\mathbf{n}}_b p_w.$

where $\hat{\mathbf{n}}_s$ and $\hat{\mathbf{n}}_b$ are normal vectors to the ice surface and bottom, and I is the unit 123 tensor (matrix). Because the component of the stress parallel to the ice surface vanishes 124 at the top and bottom (friction with the ocean and atmosphere is negligible), a very 125 good approximation is to assume that the horizontal ice velocities are independent of 126 depth [e.g., Weertman, 1957; MacAyeal and Barcilon, 1988]. Additionally, the vertical 127 scale of the floating ice is much smaller than Earth's radius r, and we therefore employ 128 the "thin shell" approximation, in which r is assumed to be constant. The very large 129 aspect ratio (thousands of km in the horizontal dimension, vs hundreds of meters in the 130 vertical) implies that the vertical velocities may be assumed to be very small relative 131 to the horizontal ones. These assumptions lead to the following approximation for the 132

X - 8

¹³³ symmetric rate of strain tensor in spherical coordinates (appendix A),

$$\dot{\boldsymbol{\epsilon}} \approx \begin{pmatrix} \frac{1}{r\sin\theta} \left(\partial_{\phi} u + v\cos\theta\right) & . & .\\ \frac{1}{2r} \left(\frac{1}{\sin\theta}\partial_{\phi} v + \sin\theta\partial_{\theta}\left(u/\sin\theta\right)\right) & \frac{1}{r}\partial_{\theta} v & .\\ 0 & 0 & \partial_{z} w \end{pmatrix}, \tag{3}$$

where entries marked by dots above the diagonal are equal to their symmetric counterparts below the diagonal. Note in particular that $\dot{\epsilon}_{\theta z} = \dot{\epsilon}_{\phi z} \approx 0$ so that $\tau_{\theta z} \approx 0$, $\tau_{\phi z} \approx 0$ as well. Following *Morland* [1987] and *MacAyeal* [1997], we integrate the above momentum equations from top to bottom and use the boundary conditions (2) to find the final set of ice shelf equations in spherical coordinates (appendix A2),

$$0 = \frac{1}{\sin\theta} \partial_{\phi} \Big[B (2 \frac{1}{\sin\theta} (\partial_{\phi} u + v \cos\theta) + \partial_{\theta} v) \Big]$$

$$+ \frac{1}{\sin\theta} \partial_{\phi} \Big[B \frac{1}{2} (\partial_{\phi} u + sin^{2} \theta \partial_{\phi} (u / \sin\theta)) \Big]$$

$$(4)$$

14

134

135

$$+ \frac{1}{\sin\theta} \partial_{\theta} \left[B \frac{1}{2} \left(\partial_{\phi} v + \sin^{2}\theta \partial_{\theta} (u/\sin\theta) \right) \right]$$

$$+ \cot\theta B \frac{1}{2} \left(\frac{1}{\sin\theta} \partial_{\phi} v + \sin\theta \partial_{\theta} (u/\sin\theta) \right) - \frac{1}{\sin\theta} g \rho_{I} (1-\mu) h h_{\phi}$$

$$= \left[B \frac{1}{2} \left(\frac{1}{\sin\theta} \partial_{\phi} v + \sin\theta \partial_{\theta} (u/\sin\theta) \right) \right]$$

$$= \left[B \frac{1}{2} \left(\frac{1}{\sin\theta} \partial_{\phi} v + \sin\theta \partial_{\theta} (u/\sin\theta) \right) \right]$$

$$= \left[B \frac{1}{2} \left(\frac{1}{\sin\theta} \partial_{\phi} v + \sin\theta \partial_{\theta} (u/\sin\theta) \right) \right]$$

$$+ \left[\frac{\sin\theta}{\sin\theta}\partial_{\theta}\left(B\sin\theta\partial_{\theta}v\right) + \partial_{\theta}\left(B\frac{\sin\theta}{\sin\theta}\partial_{\theta}\left(v\sin\theta\right)\right)\right] + \partial_{\theta}\left(B\frac{\sin\theta}{\sin\theta}\partial_{\phi}u\right)$$

$$-\cot\theta B\frac{1}{\sin\theta}\left(\partial_{\phi}u + v\cos\theta\right) - g\rho_{I}(1-\mu)hh_{\theta}$$

$$B = \frac{1}{r} h \langle A(T)^{-\frac{1}{3}} \rangle \dot{\epsilon}^{\frac{1}{3}-1}$$
(6)

$$\dot{\epsilon}^2 = \frac{1}{2} \left(\dot{\epsilon}^2_{\phi\phi} + \dot{\epsilon}^2_{\theta\theta} + (\dot{\epsilon}_{\phi\phi} + \dot{\epsilon}_{\theta\theta})^2 + 2\dot{\epsilon}^2_{\phi\theta} \right) \tag{7}$$

147

$$h_t + \frac{1}{r\sin\theta}\partial_{\phi}(uh) + \frac{1}{r\sin\theta}\partial_{\theta}(\sin\theta vh) = \kappa\nabla^2 h + S(\phi,\theta).$$
(8)

where $\mu = \rho_i / \rho_w$, and $\langle \rangle$ denotes an average over the vertical dimension, where the temperature varies linearly in depth as explained above [Goodman and Pierrehumbert, 2003]. An improved and more consistent treatment of the vertical averaging procedure is described by Campbell et al. [2011]. The above thickness equation is a statement of mass conservation, and the diffusion term is included for numerical reasons to make sure the X - 10 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

¹⁵⁶ solution is smooth. While we use the diffusion term merely as a numerical aid, it may ¹⁵⁷ also crudely represent snowdrift at the surface, which would tend to smooth thickness ¹⁵⁸ variations (although snow fall rate should be extremely small in a Snowball scenario). We ¹⁵⁹ keep the diffusion coefficient as small as allowed by the numerics, and the diffusion term is ¹⁶⁰ accordingly negligible relative to thickness advection throughout the domain. The forcing ¹⁶¹ $S(\phi, \theta)$ represents the accumulated effect of surface and internal melting and sublimation, ¹⁶² as well as basal freezing and melting of ice.

The boundary conditions for the above equations are no normal flow into the north and south boundaries, and periodic boundary conditions in the east-west direction. In addition we prescribe no normal-flow and no slip conditions for the velocity field at continental boundaries, which is equivalent to assuming coastal boundaries are vertical. Zero normal derivatives of the thickness are prescribed for the advection-diffusion thickness equation at the north and south boundaries as well as at continental boundaries.

It is useful to write explicitly the equations for the axisymmetric one-dimensional model which ignores continents, in which case there is no dependence on ϕ and the zonal velocity u is assumed to vanish,

$$0 = \left[\frac{1}{\sin\theta}\partial_{\theta} \left(B\sin\theta\partial_{\theta}v\right) + \partial_{\theta}\left(B\frac{1}{\sin\theta}\partial_{\theta}(v\sin\theta)\right)$$
(9)

$$-\cot^2\theta Bv \bigg] - g\rho_I(1-\mu)hh_\theta \tag{10}$$

$$B = \frac{1}{r}h\langle A(T)^{-\frac{1}{3}}\rangle\dot{\epsilon}^{\frac{1}{3}-1}$$

$$\dot{\epsilon}^2 = \dot{\epsilon}^2_{\phi\phi} + \dot{\epsilon}^2_{\theta\theta} + \dot{\epsilon}^2_{zz} \tag{11}$$

$$\dot{\epsilon}_{zz} = -(\dot{\epsilon}_{\phi\phi} + \dot{\epsilon}_{\theta\theta}) \tag{12}$$

$$h_t + \frac{1}{r\sin\theta} \partial_\theta(\sin\theta vh) = \kappa \nabla^2 h + S(\theta).$$
(13)

175

176

March 12, 2012, 6:36pm

This one-dimensional model is somewhat different from that used in previous studies [e.g., 179 Goodman and Pierrehumbert, 2003; Goodman, 2006; Pollard and Kasting, 2005, 2006]. 180 First, it more accurately accounts for the lateral geometry following the *Morland* [1987] 181 and MacAyeal [1997] formulation, which leads to the second term in the above momentum 182 equation. Second, it includes the spherical coordinate correction to the divergence of the 183 stress tensor (third term in the momentum equation). The spherical coordinate correction 184 term arises mathematically from the additional set of geometric correction terms in the 185 expression of the divergence of a second order tensor relative to that of a vector (appendix 186 B). Physically this term is due to the stress element $\tau_{\phi\phi}$ appearing in the θ (meridional) 187 direction momentum balance (see term including $\tau_{\phi\phi}$ in equation (A10)). This stress 188 element represents the unit force in the ϕ direction, acting on a unit surface perpendicular 189 to this same direction. It is non zero even in the axisymmetric case because $\dot{\epsilon}_{\phi\phi}$ does not 190 vanish in this case as explained below. To see why a stress element representing a force in 191 the ϕ direction appears in the momentum equation for the θ direction, consider a small 192 volume element in spherical coordinates, $(d\phi, d\theta, dr)$. Note that the faces of this element 193 that are perpendicular to the ϕ direction have a slightly different northward slope at 194 longitudes ϕ and at $\phi + d\phi$. As a result, the net force in the ϕ direction due to the sum of 195 $\tau_{\phi\phi}$ acting on these faces has a component in the θ direction, leading to the above term. 196 Finally, this equation includes the contribution of the non-vanishing $\dot{\epsilon}_{\phi\phi}$ element in the 197 effective viscosity, again due to the spherical coordinates used as explained after equation 198 (3). Goodman and Pierrehumbert [2003], as well as Li and Pierrehumbert [2011] noted 199 the existence of this effect, but argued that it was inconsequential in comparison with 200 the much larger effect of temperature on ice rheology, and the much larger uncertainty 201

X - 12 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

²⁰² in ice rheology coefficients. Unlike in Cartesian coordinates, $\dot{\epsilon}_{\phi\phi}$ does not vanish in the ²⁰³ axisymmetric case where there is no dependence on ϕ and where u = 0. It is equal then to ²⁰⁴ $v \cot \theta/r$, representing the fact that a fluid line element oriented in the east-west direction ²⁰⁵ and advected by a uniform northward flow will shrink due to the convergence of the ²⁰⁶ longitude lines. This modifies the effective viscosity in an important way not accounted ²⁰⁷ for in previous models of Snowball ice flow.

This fuller treatment of spherical coordinates precludes the explicit integration of the velocity equation and the derivation of a single equation for the thickness, as was possible using the simpler equations of previous studies. Nevertheless the fuller equations (9)-(13) are easily solved numerically using a combination of a tri-diagonal solver for the momentum equation [iterated to account for the nonlinear effective viscosity, *MacAyeal*, 1997] and time stepping of the thickness equation.

Eliminating the spherical corrections and the more accurate treatment of the bottom 214 and surface slopes and boundary conditions (equivalent to making a small-slope approxi-215 mation at these boundaries), our 1d equation reduces to a simpler one, in which only the 216 first term is left in the square brackets in the momentum equation (9), in addition to the 217 pressure gradient term. Neglecting also the contribution of $\dot{\epsilon}_{\phi\phi}$ to the rate of strain, we get 218 a simpler equation which may be integrated once in co-latitude to lead to the Goodman 219 and Pierrehumbert [2003] equation. The constant of integration from this first integra-220 tion then plays a parallel role to that of the "body force" introduced by those authors 221 to represent the pressure force due to the collision of ice from the north and south hemi-222 spheres, and to allow the velocity to vanish in the case of symmetric forcing with respect 223 to the equator. Instead of postulating this force, we can use the constants of integration 224

²²⁵ to satisfy the boundary conditions of vanishing velocity at the north and south ends of ²²⁶ the domain, and when the forcing $S(\theta)$ is symmetric in latitude, the equatorial velocity ²²⁷ vanishes as expected. Using a constant of integration instead of a prescribed body force ²²⁸ is also discussed in the supplementary material of *Li and Pierrehumbert* [2011].

We solve the 2d and 1d model equations numerically using finite difference approxima-229 tion over a near-global domain from 80°S to 80°N, prescribing no-normal flow into the 230 northern and southern boundaries. We use a resolution of 176×176 grid points in the 2d 231 cases shown in the figures below, and of 89 grid points in the 1d case. The finite difference 232 formulation is based on an A-grid (all variables defined at the same point) and center dif-233 ferencing. In the grid points adjacent to land masses, we estimate the pressure gradient 234 terms and the effective viscosity using the one-sided finite difference approximation. The 235 momentum equations are solved following standard procedure by iterating on the effective 236 viscosity [MacAyeal, 1997]. 237

The prescribed time-independent, latitude-dependent, net melting/ freezing/ sublima-238 tion are from the *Pollard and Kasting* [2005] model for the case of bubbly ice (their Fig. 4c, 239 dashed lines, smoothed before used here). We do not differentiate between surface and 240 basal melting/ freezing, and therefore do not include feedbacks between basal melting/ 241 freezing and ice thickness via the balance between heat diffusion within the ice cover 242 and geothermal heat flux [Goodman and Pierrehumbert, 2003]. The global integral of the 243 specified source function vanishes, and the flow and source function can therefore only 244 redistribute thickness across the domain. As expected in the absence of the thickness-245 dependent basal melting, the domain-averaged thickness is set by the initial conditions, 246

X - 14 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

and is therefore not uniquely determined by the model parameters. We initialize integra tions with an average thickness of 1000 meters.

Because our forcing corresponds to the bubbly (reflecting) ice case of Pollard and Kast-249 ing [2005], the thickness variations we calculate may be underestimating those that could 250 be calculated by including additional effects involving the optical properties of the ice etc. 251 Ignoring other feedbacks, such as dependence of basal melting/ freezing on ice thickness 252 may also significantly affect our solution. Addressing these additional effects well would 253 require a full ocean general circulation model that would calculate the ocean heat trans-254 ports and temperature field and, from that, the basal melting and freezing. This is left 255 for a future study. 256

²⁵⁷ The model code is written in Matlab and is available at www.seas.harvard.edu/climate/eli/Downloads.

3. Numerical results

Table 1 lists the different model experiments we have performed. All shown results 258 represent the steady state model solution, obtained by running the model for at least 259 one hundred thousand years. The results of the 1d model, which ignores land masses, 260 are shown in Fig. 1. Consistent with previous studies and with the scaling arguments 261 given in section 4.2, this model predicts a very small thickness difference between the 262 pole and the equator when optical/ dust effect are not included (comparable to *Pollard*) 263 and Kasting [2005] Fig. 4f, dash line representing bubbly ice; note the discussion in Li264 and Pierrehumbert [2011] regarding the larger difference found in Goodman and Pierre-265 humbert [2003]). The model results show an ice thickness difference of about 100 meters 266 between the equator and pole for the cold case, and only 40 meters for the warm case. 267 The warmer temperatures make the ice softer, as expected, and therefore lead to even 268

March 12, 2012, 6:36pm

smaller thickness gradients. The small meridional ice thickness gradient in both cases 269 demonstrates the effectiveness of the ice flow in effectively homogenizing ice thickness, as 270 pointed out by Goodman and Pierrehumbert [2003]. Such a uniformly thick ice does not 271 allow light penetration into the ocean, with implications to photosynthesis as discussed in 272 the introduction. Our two-dimensional model produces identical results to the 1d model 273 when no continent is included (experiment 5, Table 1, not shown). 274

The results of the two-dimensional model for a continental configuration roughly following a Neoproterozoic reconstruction for 630 Myr [Li et al., 2008] are shown in Fig. 2. The land configuration was modified to eliminate features such as single grid point openings in topography that may lead to numerical problems. The figure shows the flow, thickness and \log_{10} of the effective viscosity,

$$\nu_{\rm eff} = \langle A(T)^{-\frac{1}{3}} \rangle \dot{\epsilon}^{\frac{1}{3}-1} \tag{14}$$

for both a "warm" surface temperature corresponding to the high- CO_2 near-melting case 275 and for the cold, $low-CO_2$ case. 276

The thickness variations are clearly much larger than in the axisymmetric case. Because 277 the constricted ocean area is small, the zonally averaged thickness and velocity fields may 278 not be very different from those of the one dimensional model, but the local thickness 279 differences are clearly much larger. This is especially evident in constricted areas such as 280 between the main land mass and the two small continents to the east and west of it, and 281 in particular between the global ocean and the marginal (constricted) sea in the middle 282 of the major land mass. In this latter case the ice flow through the narrow passages needs 283 to balance to total ice melting and evaporation within the constricted sea. Therefore 284 the larger the area of the sea and the narrower are the straits, the faster is the ice flow 285

X - 16 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

expected to be. These results are consistent with the general message of *Campbell et al.* 286 [2011] [see also Warren et al., 2002] that when the flow is limited by the continental 287 geometry, significant ice thickness differences develop. We note that in addition to these 288 constricted ocean locations, Fig. 2 also shows significant thickness variations south of the 289 main continent, especially in the "cold" case (upper right panel). The thickness variations 290 in this specific location are likely affected by the artificial boundary at 80N placed there 291 in order to avoid the coordinate singularity at the pole, yet these results demonstrate that 292 thickness variations due to the interaction of geometry and flow occur in a wider range of 293 situations than was possible to discuss in previous studies. 294

The thickness variations are again larger for the colder temperature case, when the ice 295 is stiffer and requires larger pressure (thickness) gradients to drive the flow needed to 296 balance net sublimation/ melting within the constricted sea. The next section provides a 297 scaling expression for this effect as well as for the global axisymmetric case. Note that the 298 velocity field is not very different between the warm and cold runs (see maximum velocities 200 indicated in Fig. 2) and this may be understood as follows. The specified source/ sink 300 function $S(\phi, \theta)$ needs to be balanced by ice transport convergence, $\nabla \cdot (\mathbf{u}h)$. Given that 301 the source function is constant in our runs, and if the thickness fields are not very different 302 to zeroth order, this implies that the velocity field is, to a good approximation, set by 303 the source function. Changes in the ice thickness between different runs would lead to 304 changes in the velocity set by the source function. In turn, the thickness gradients that 305 are required to drive this velocity field do depend on the ice viscosity and therefore on the 306 temperature, as can be seen in Figs. 1 and 2. It is possible to use our model results to 307 identify and analyze the weak dependence of the flow field on the temperature, because 308

the model does not include many other processes that could mask this result. This is an advantage of neglecting effects such as the dependence of the basal melting and freezing on the ice thickness and the effects of non-bubbly ice on the absorption of radiation.

The temperature field implied by our model formulation is a three dimensional com-312 bination of the prescribed meridional surface temperature profile shown in the middle 313 panels of Fig. 1, and the assumed linear vertical temperature profile from the prescribed 314 surface temperature to the (assumed constant) melting temperature at the base of the 315 ice. The ice flow field advects this temperature field and should lead, in principle, to a 316 complex 3d temperature distribution. This advection effect is neglected here, as well as 317 strain heating generated within the ice, and horizontal diffusion. We can estimate how 318 important the advection might be in different areas of the ice flow. Neglecting this ad-319 vection is a sensible approximation only if the time scale of changes to the temperature 320 due to vertical diffusion, which sets the linear vertical temperature profile, is shorter than 321 that due to meridional advection. We therefore plot the following non-dimensional ratio, 322 effectively a Peclet number, in Fig. 3, 323

325

$$Pe = \frac{v(r\sin\theta)^{-1}\partial(\sin\theta T)/\partial\theta}{\kappa_i \partial^2 T/\partial z^2} \approx \frac{v(r\sin\theta)^{-1}\partial(\sin\theta T)/\partial\theta}{\kappa_i (T_{surface} - T_{freezing})/h^2}$$
(15)

where κ_i is the molecular heat diffusivity in ice, different from the (mostly numerical) horizontal diffusivity term appearing above in the mass conservation/ thickness equation. Fig. 3 shows that while temperature advection may be neglected in most areas (where the ratio is significantly smaller than one), it is not negligible in some key areas, in particular in narrow straights characterized by more rapid flow, where the ratio may be closer to, or even larger than, one. While these areas are quite isolated, it is clear that neglecting the effects of advection on the ice temperature is not justified there. X - 18 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

Comparing the 2d results based on a 176×176 grid to a solution on an 89×89 grid 333 (experiments 7, 8 vs 9,10, Table 1, Figs not shown) shows that differences are not large. 334 Ice thickness within the constricted sea is about 50 meters thinner in the coarser runs, 335 indicating that numerical convergence of the solution as function of the model resolution 336 has not been completely reached (as is often the case in global climate models). This is 337 most likely due to insufficient resolution within the channels leading to the constricted 338 sea. This problem, which often occurs in ocean models that cannot resolve critical narrow 339 straights and sills (e.g., Straits of Gibraltar), may be resolved in future studies by either 340 local grid refinement or by a parameterization of the channel flow, replacing the attempt 341 to explicitly resolve the flow there. These solutions are beyond the scope of the present 342 study. 343

4. Scaling estimate of ice thickness variations

In this section we consider scaling estimate for thickness variations in two cases: a constricted sea fed by a long narrow channel, and a global, axisymmetric ocean.

4.1. Constricted sea

³⁴⁶ Consider a sea of area \mathcal{A} , linked to the ocean via a channel of length L and width W³⁴⁷ such that $L \gg W$. The ice thickness inside the sea, h_s , may be assumed uniform as a result ³⁴⁸ of efficient ice flow equilibration, and we denote the open ocean ice thickness outside of the ³⁴⁹ channel h_o . Denoting the ice velocity in the channel as V and the average sublimation/ ³⁵⁰ melt rate within the sea as b, the mass balance scaling for the ice cover of the sea is given ³⁵¹ by,

352 353

$$Vh_oW \sim \mathcal{A}b.$$
 (16)

DRAFT

March 12, 2012, 6:36pm

Another relation may be obtained from the ice shelf momentum balance equations [Mor-354 land, 1987; MacAyeal, 1997]. Let y be the along-channel coordinate and assume that 355 u = 0; let also n be the Glen's flow law constant taken in our model equations above to 356 be 3. The ice-shelf along-channel (v) momentum equation, 357

358
$$0 = \partial_x (B\frac{1}{2}(u_y + v_x)) + \partial_y (B(u_x + 2v_y)) - g\rho_I (1 - \mu)hh_y$$

359

36

$$B \equiv h \langle A(T)^{-\frac{1}{n}} \rangle \dot{\epsilon}^{\frac{1}{n}-1}$$

$$\dot{\epsilon}^{2} \approx \frac{1}{2} \left(u_{x}^{2} + v_{y}^{2} + (u_{x} + v_{y})^{2} + \frac{1}{2} (u_{y} + v_{x})^{2} \right),$$

reduces to 362

$$0 = \partial_x (B\frac{1}{2}v_x) + \partial_y (B2v_y) - g\rho_I (1-\mu)hh_y$$

$$B \equiv h \langle A(T)^{-\frac{1}{n}} \rangle \dot{\epsilon}^{\frac{1}{n}-1}$$

$$\dot{\epsilon}^{2} \approx \frac{1}{2} \left(2v_{y}^{2} + \frac{1}{2}v_{x}^{2} \right) \approx \frac{1}{4}v_{x}^{2},$$

where the assumed large channel aspect ratio, $L/W \gg 1$ leads to $\dot{\epsilon} \approx v_x/2$ on the last line 367 above. The second term in the y-momentum equation may be neglected if $L \gg W$ because 368 it scales with L^{-2} while the first terms scales with W^{-2} . Assuming the velocity vanishes 369 at the sides of the channel and is maximal at its center, we scale the cross-channel shear 370 as $v_x \sim V/(W/2)$, so that the momentum equation scales as, 371

$$\frac{BV}{2(W/2)^2} \sim g\rho_I (1-\mu) h_o (h_o - h_s)/L.$$
(17)

Scaling the effective viscosity as 374

$$B \sim h_o \langle A(T)^{-\frac{1}{n}} \rangle \left(\frac{1}{2} \frac{V}{W/2}\right)^{\frac{1}{n}-1},$$
(18)

DRAFT

March 12, 2012, 6:36pm

and substituting the velocity scale from the mass balance equation, we find an estimate for the thickness difference along the channel,

$$h_o - h_s \sim \frac{2L\langle A(T)^{-\frac{1}{n}} \rangle}{Wg\rho_I(1 - \rho_i/\rho_w)} \left(\frac{\mathcal{A}b}{h_0 W^2}\right)^{\frac{1}{n}}.$$
(19)

This scaling is to be compared with the formula for an ice invasion length in rectangular-381 shaped (Red-Sea like) marginal sea used by *Campbell et al.* [2011] following Nye [1965]. 382 The advantage of their formulation is that it is based on an exact formula rather than 383 crude scaling as done here. The scaling here, though, accounts for the case where the 384 constricted sea is not rectangular but has a wider area fed by a narrow channel, as mo-385 tivated by the Neoproterozoic land mass reconstruction shown in Fig. 2. It is clear from 386 this scaling estimate that a constricted sea located in the low-latitudes where there is net 387 ice sublimation and melting, will lead to higher thickness variations (thinner ice in the 388 constricted sea) if the channel is longer (large L), narrower (small W), or if the sea itself 389 has a larger area (\mathcal{A}) , larger melt rate (b) or if the ice temperature is colder (via the de-390 pendence on A(T), note that A(T) increases with temperature, and therefore $\langle A(T)^{-\frac{1}{n}} \rangle$ 391 gets smaller; that is, warmer temperatures lead to softer ice and to smaller thickness 392 differences). 393

Substituting order-of-magnitude values for the parameters based on the "warm" solution for constricted sea in the Neoproterozoic land configuration (Fig. 2), $\mathcal{A} = (4000 \cdot 10^3)^2$ $(m^2); b = 6 \cdot 10^{-3}/(365 \cdot 24 \cdot 3600) (m/s); L = 2500 \cdot 10^3 (m); W = 1000 \cdot 10^3 (m); h_o = 1000$ $(m); g = 9.8 (m/s^2); \rho_i = 900 (kg/m^3); \rho_w = 1024 (kg/m^3); T_f = 273.16 (K); T_s = T_f - 30$ (K); n = 3; where we chose the surface temperature to represent the location of the main channel leading to the constricted sea in the warm case shown in the upper left panel of Fig. 2, we find $h_o - h_s \sim 108m$. This estimate is of the same order, yet smaller than that

DRAFT

379 380

March 12, 2012, 6:36pm

calculated by the numerical solution (compare to the "warm" solution on the left hand 401 side of Fig. 2). Note that our assumption of $L \gg W$ isn't strictly satisfied. We calculated 402 the thickness difference along the channel assuming a single channel but the above land 403 configuration actually has two such channels, so that the comparison is somewhat vague. 404 It is possible that a marginal grid resolution in the passages leading to the constricted sea 405 biases the resolution, and the scaling itself cannot be expected to yield exact results, of 406 course. But the scaling does make it clear that significantly larger thickness differences are 407 to be expected in the case of a constricted marginal sea than when there are no marginal 408 seas, e.g., because continents are ignored. Scaling for the case of no continents is presented 409 in the following section. 410

4.2. Global ocean, no continents

The 1d momentum and steady mass conservation equations (9) and (13) scale, correspondingly, as

$$2\frac{1}{r}h\langle A(T)^{-\frac{1}{3}}\rangle \left(\frac{v}{r}\right)^{\frac{1}{n}} \sim g\rho_I(1-\rho_I/\rho_w)h\Delta h/r$$

419 420

$$vh/r \sim \Delta S$$

where the factor two on the left hand side of the momentum equation accounts for the first two terms in (9) and $\Delta S = S_{max} - S_{min}$. Together, these lead to a scaling for the thickness difference between the equator and the pole, Δh ,

$$\Delta h \sim \frac{2\langle A(T)^{-\frac{1}{3}}\rangle \left(\Delta S/[h]\right)^{\frac{1}{n}}}{g\rho_I(1-\rho_I/\rho_w)} \tag{20}$$

⁴²¹ Substituting order of magnitude scales, $\Delta S = 12 \cdot 10^{-3} / yr(m/s)$; [h] = 1000(m); g =⁴²² 9.8 (m/s^2) ; $\rho_i = 900(kg/m^3)$; $\rho_w = 1024(kg/m^3)$; $T_f = 273.16(K)$; $T_s = T_f - 30(K)$; ⁴²³ n = 3; we find $\Delta h \sim 34$ m. This estimate is quite close to the numerical solution of the "warm" 1d case in Fig. 1. Rather than specifying the thickness scale as we did above, one could calculate it by balancing the diffusive heat flux through the ice with the geothermal heat flux F_{geo} , such that $[h] = \kappa \Delta T / F_{geo}$. Overall, the scaling estimates of this and the previous sections predict a much weaker thickness difference if continents are neglected, consistent with the numerical solutions.

5. Conclusions

Ice flow over a Snowball ocean was shown to be an important factor participating in 429 the determination of ice thickness over the ocean [Goodman and Pierrehumbert, 2003], 430 and has received significant attention in recent years [Warren et al., 2002; Pollard and 431 Kasting, 2005; Goodman, 2006; Warren and Brandt, 2006; Pollard and Kasting, 2006; 432 Campbell et al., 2011; Li and Pierrehumbert, 2011]. These studies all use local models or 433 one-dimensional global (latitude-only) models, formulated in a way that was difficult to 434 extend to two dimensions (both longitude and latitude). This paper attempts to make 435 progress on two different fronts related to this ice flow problem. First, we study the 436 effects of continental constriction on ice flow and ice thickness in an ice-covered ocean in 437 a Snowball-Earth scenario using a global model with reconstructed Neoproterozoic land-438 mass configuration. Second, we provide a formulation of the ice flow problem in two 439 dimensions on a sphere that should allow coupling such ice flow models to ocean and 440 atmospheric general circulation models. This formulation is a very simple extension of 441 the well known ice-shelf equations from glaciology [Morland, 1987; MacAyeal, 1997, e.g.] 442 to spherical coordinates. 443

Campbell et al. [2011] used a formula derived by Nye [1965] to show that the invasion by
ice into an idealized rectangular-shaped marginal sea (Red-Sea like) is limited by friction

with the side walls and that this may lead to significant ice thickness variations within 446 such a sea in regions of net sublimation. Our numerical simulations show that, consistent 447 with the original idea of *Campbell et al.* [2011], continental constriction indeed leads to 448 ice thickness variations in additional cases. This includes relatively narrow areas between 449 sub-continents, and marginal seas whose entrance is constricted by land mass geometry. 450 In addition to numerical solutions, we present scaling estimates of the thickness variations 451 in both the case of a global ocean with no continents and in the case of a marginal sea 452 fed by a relatively narrow channel. The scaling estimates are compared to the numerical 453 solutions and are found to somewhat underestimate them, but are of the right order of 454 magnitude. 455

We formulated the ice flow problem starting with the equations of motion (Stokes 456 equation) rather than from the *Weertman* [1957] estimate for the deformation rate of 457 ice shelves. This allowed us to extend the formulation to two dimensions, which is not 458 possible starting from the Weertman deformation rate formula. In addition, we show that 459 in a model that depends on latitude only, a careful formulation of the lateral geometry and 460 boundary conditions following Morland [1987]; MacAyeal and Barcilon [1988]; MacAyeal 461 [1989, 1997], as well as the effects of spherical coordinates, leads to additional terms 462 in the model equations which were not included in previous studies. In particular, our 463 formulation involves two integrations of the momentum equations in order to solve for 464 the ice velocity. The constants of integration play a role parallel to that of the body force 465 introduced by *Goodman and Pierrehumbert* [2003], allowing the meridional ice velocity 466 to vanish at the equator in a model that's symmetric about the equator. We emphasize 467 that the main qualitative result of the works which pioneered the study of ice flow in 468

X - 24 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

⁴⁶⁹ a Snowball ocean is still valid: ice flow effectively homogenizes ice thickness across the ⁴⁷⁰ global ocean where the flow is not constricted by continents.

While we were able to make significant progress in several ways, many related and im-471 portant issues remain open. Our model ignores the flow of land ice toward the constricted 472 sea. We anticipate that an attempt to simulate ice flow in a global ocean into marginal 473 seas whose opening is small will run into numerical resolution limits. Rather than in-474 creasing the global resolution, one would need to resort to either local grid refinement, or 475 to a parameterization of the ice flow in narrow straights, as is routinely done in coarse 476 resolution ocean models that cannot resolve critical narrow straights and sills (e.g., Straits 477 of Gibraltar). The poles pose a problem to the numerics in standard spherical coordinates 478 as they do in oceanic and atmospheric models, and one could resort to alternative grids 479 where the poles are moved to over a land mass [e.g. Voigt et al., 2011], or where Earth's 480 surface is mapped into a cube as is done in current state-of-the-art ocean models [Adcroft 481 et al., 2004. 482

Having concentrated on ice flow alone, we ignored all thermodynamic, dust and optical 483 effects that are known to be important processes in setting ice thickness in a Snowball 484 scenario [Warren et al., 2002; Goodman and Pierrehumbert, 2003; McKay, 2000; Pollard 485 and Kasting, 2005, 2006; Warren and Brandt, 2006; Goodman, 2006; Abbot and Pier-486 rehumbert, 2010; Li and Pierrehumbert, 2011; Pierrehumbert et al., 2011]. Instead, we 487 prescribed the net source/ sink of ice due to accumulation, freezing, melting and subli-488 mation as time independent forcing fields based on the values calculated by *Pollard and* 489 Kasting [2005]. While this allowed us to isolate the effects of ice flow, the ignored addi-490 tional factors can make the thickness variations significantly larger, possibly leading to 491

⁴⁹² thin ice cover over constricted seas and low-latitudes, with implications for survival of life ⁴⁹³ discussed by *Campbell et al.* [2011]. We cannot discuss such implications given that we ⁴⁹⁴ neglected these important factors.

It should be noted that the glaciological literature has dealt extensively with ice shelves, their dynamics, collapse, existence of rifting and fracturing during the flow through channels [Doake et al., 1998; Doake and Vaughan, 1991; MacAyeal et al., 2003; Rott et al., 1996; Vieli et al., 2006; Weis et al., 1999; Van-Der-Veen, 1999, e.g.,]. The resulting lessons are of obvious relevance to the dynamics of ice flow over a Snowball ocean, as well as to the existence of refuges within ice shelf cracks.

Given these many idealizations, we emphasize that this study is meant to be a process study focusing on one specific dynamical factor, not a realistic simulation of Neoproterozoic ice thickness. We also assume ice thickness to be large everywhere, and the formulation here would need to be extended if thin ice cover or ice-free ocean develops, or for a study of transient Snowball initiation and an invasion of the ocean by thick ice.

In spite of its obvious limitations, this study is a first step toward coupling Snowball ice flow models to general circulation ocean and atmospheric models. This, in turn, will allow an improved representation of the basal and surface melting, freezing sublimation and snow accumulation and should help making these models more accurate.

Appendix A: Derivation of model equations

A1. Surface and bottom boundary conditions

The upper and lower boundary momentum conditions may be written [MacAyeal, 1997],

$$\boldsymbol{\sigma} \cdot \hat{\mathbf{n}}_s = 0, \tag{A1}$$

$$\mathbf{\sigma}\cdot\hat{\mathbf{n}}_{b}=-\hat{\mathbf{n}}_{b}p$$

where \mathbf{n}_s and \mathbf{n}_b are the outward-pointing normal vectors at the surface and the bottom, respectively. The stress tensor element σ_{ij} is the force in the *i* direction acting on a face perpendicular to the *j* direction, so that $\sigma_{ij}n_j$ is the total force in the *i* direction on a unit area along the ice surface. This force vanishes at the surface and is equal to the hydrostatic water pressure p_w at the bottom of the ice. Defining the deviatoric stress as $\tau_{ij} = \sigma_{ij} - \delta_{ij} \frac{1}{3} \sigma_{kk} = \sigma_{ij} + p \delta_{ij}$ (where δ_{ij} is the Kronecker delta, and the pressure is defined as $p = -\frac{1}{3} \sigma_{kk}$), leads to the equivalent form of the boundary conditions

$$(\boldsymbol{\tau} - p\mathbf{I}) \cdot \hat{\mathbf{n}}_s = 0, \tag{A2}$$

$$\sum_{\frac{522}{523}} (\boldsymbol{\tau} - p\mathbf{I}) \cdot \hat{\mathbf{n}}_b = -\hat{\mathbf{n}}_b p_w$$

The normal vector to the surface elevation $s(\phi, \theta)$ is given by the gradient of $f(\phi, \theta, z) = z - s(\phi, \theta)$,

$$\hat{\mathbf{n}} = \frac{\nabla f}{\|\nabla f\|} = \frac{\left(-\frac{1}{r\sin\theta}s_{\phi}, -\frac{1}{r}s_{\theta}, 1\right)}{\|\left(-\frac{1}{r\sin\theta}s_{\phi}, -\frac{1}{r}s_{\theta}, 1\right)\|}.$$
(A3)

⁵²⁸ The boundary conditions (2) and (A2) in spherical coordinates then take the form,

$$(\tau_{\phi\phi} - p)\frac{1}{r\sin\theta}s_{\phi} + \tau_{\phi\theta}\frac{1}{r}s_{\theta} - \tau_{\phi z} = 0 \qquad z = s \qquad (A4)$$

$$\tau_{\theta\phi} \frac{1}{r\sin\theta} s_{\phi} + (\tau_{\theta\theta} - p) \frac{1}{r} s_{\theta} - \tau_{\theta z} = 0 \qquad z = s$$

$$\tau_{z\phi} \frac{1}{r\sin\theta} s_{\phi} + \tau_{z\theta} \frac{1}{r} s_{\theta} - (\tau_{zz} - p) = 0 \qquad z = s$$

⁵³²
$$(\tau_{\phi\phi} - p)\frac{1}{r\sin\theta}b_{\phi} + \tau_{\phi\theta}\frac{1}{r}b_{\theta} - \tau_{\phi z} = -\frac{1}{r\sin\theta}b_{\phi}g\rho_{w}\mu h \qquad z = b$$

$$\tau_{\theta\phi} \frac{1}{r\sin\theta} b_{\phi} + (\tau_{\theta\theta} - p) \frac{1}{r} b_{\theta} - \tau_{\theta z} = -\frac{1}{r} b_{\theta} g \rho_w \mu h \qquad z = b$$

$$\tau_{z\phi} \frac{1}{r\sin\theta} b_{\phi} + \tau_{z\theta} \frac{1}{r} b_{\theta} - (\tau_{zz} - p) = g\rho_w \mu h \qquad z = b$$

⁵³⁶ where $\mu = \rho_i / \rho_w$ as above.

A2. Ice shelf-equations in spherical coordinates

⁵³⁷ This derivation follows *Morland* [1987] and *MacAyeal* [1997], except for the use of ⁵³⁸ spherical coordinates here. (Alternatively, the same results can be derived by starting ⁵³⁹ from the invariant formulation of *Schoof* [2006] and using expressions for the covariant ⁵⁴⁰ derivatives in spherical coordinates). Let the coordinates (longitude, co-latitude, vertical) ⁵⁴¹ be denoted by (ϕ, θ, r) and the corresponding velocities be (u, v, w). Below, when we ⁵⁴² make the "thin shell" approximation, we switch to the coordinates (ϕ, θ, z) and treat r as ⁵⁴³ a constant. The gradient, divergence of a vector and Laplacian are,

5

$$\nabla = \left(\frac{1}{r\sin\theta}\partial_{\phi}, \frac{1}{r}\partial_{\theta}, \partial_{r}\right) \tag{A5}$$

545

546

$$\nabla \cdot \mathbf{v} = \frac{1}{r \sin \theta} \partial_{\phi} u + \frac{1}{r \sin \theta} \partial_{\theta} (\sin \theta v) + \frac{1}{r^2} \partial_r (r^2 w)$$
$$\approx \frac{1}{r \sin \theta} \partial_{\phi} u + \frac{1}{r \sin \theta} \partial_{\theta} (\sin \theta v) + \partial_z w$$

$$\Delta f = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial f}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial f}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 f}{\partial \phi^2}.$$

$$\approx \partial_{zz} f + \frac{1}{r^2 \sin \theta} \partial_{\theta} \left(\sin \theta \partial_{\theta} f \right) + \frac{1}{r^2 \sin^2 \theta} \partial_{\phi\phi} f.$$

DRAFT

March 12, 2012, 6:36pm

X - 28 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

where we have made the approximation of a thin shell of ice whose thickness is much smaller than Earth's radius, replacing r-derivatives with derivatives with respect to a local vertical coordinate z and treating r as a constant equal to Earth's radius. The (symmetric) rate of strain is (its elements above the diagonal are omitted),

554

555

556

$$\dot{\boldsymbol{\epsilon}} = \begin{pmatrix} \dot{\epsilon}_{\phi\phi} & \dot{\epsilon}_{\phi\theta} & \dot{\epsilon}_{\phi r} \\ \dot{\epsilon}_{\theta\phi} & \dot{\epsilon}_{\theta\theta} & \dot{\epsilon}_{\theta r} \\ \dot{\epsilon}_{r\phi} & \dot{\epsilon}_{r\theta} & \dot{\epsilon}_{rr} \end{pmatrix}$$

$$= \begin{pmatrix} \frac{1}{r\sin\theta} \left(\partial_{\phi} u + w\sin\theta + v\cos\theta \right) & . & . \\ \frac{1}{2r} \left(\frac{1}{\sin\theta} \partial_{\phi} v + \sin\theta \partial_{\theta} (u/\sin\theta) \right) & \frac{1}{r} \left(\partial_{\theta} v + w \right) & . \\ \frac{1}{2} \left(\frac{1}{r\sin\theta} \partial_{\phi} w + r \partial_{r} (u/r) \right) & \frac{1}{2} \left(\frac{1}{r} \partial_{\theta} w + r \partial_{r} (v/r) \right) & \partial_{r} w \end{pmatrix}.$$
(A6)

Simplifying the rate of strain tensor using the thin shell approximation (e.g., $\frac{1}{r^2}\partial_r(r^2w) \approx \partial_z w$ and neglecting w_{θ}/r) as well as using the ice-shelf approximation of neglecting $\dot{\epsilon}_{\theta z}$, $\dot{\epsilon}_{\phi z}$, and assuming the horizontal velocities are z-independent and much larger than the vertical velocity,

$$\dot{\boldsymbol{\epsilon}} \approx \begin{pmatrix} \frac{1}{r\sin\theta} \left(\partial_{\phi} u + v\cos\theta\right) & . & .\\ \frac{1}{2r} \left(\frac{1}{\sin\theta} \partial_{\phi} v + \sin\theta \partial_{\theta} (u/\sin\theta)\right) & \frac{1}{r} \partial_{\theta} v & .\\ 0 & 0 & \partial_{z} w \end{pmatrix}.$$
(A7)

The momentum equations in vector form (1) are written explicitly in component form in spherical coordinates as,

565

$$0 = -\frac{1}{r\sin\theta}\partial_{\phi}p + \frac{1}{r\sin\theta}\partial_{\phi}\tau_{\phi\phi} + \frac{1}{r\sin\theta}\partial_{\theta}(\sin\theta\tau_{\theta\phi}) + \frac{1}{r^{2}}\partial_{r}(r^{2}\tau_{r\phi})$$
(A8)
+ $\frac{\tau_{r\phi}}{r} + \frac{\cot\theta}{r}\tau_{\theta\phi}$

566

$$0 = -\frac{1}{r}\partial_{\theta}p + \frac{1}{r\sin\theta}\partial_{\phi}\tau_{\phi\theta} + \frac{1}{r\sin\theta}\partial_{\theta}(\sin\theta\tau_{\theta\theta}) + \frac{1}{r^{2}}\partial_{r}(r^{2}\tau_{r\theta})$$

$$+\frac{\tau_{r\theta}}{r} - \frac{\cot\theta}{r}\tau_{\phi\phi}$$

$$0 = -\partial_r p - g\rho_I + \frac{1}{r\sin\theta}\partial_\phi(\tau_{r\phi}) + \frac{1}{r\sin\theta}\partial_\theta(\sin\theta\tau_{r\theta}) + \frac{1}{r^2}\partial_r(r^2\tau_{rr})$$

$$\begin{array}{c} _{570} \\ _{571} \end{array} \qquad -\frac{\tau_{\theta\theta} + \tau_{\phi\phi}}{r}$$

where the divergence of a second order tensor in curvilinear coordinates contains a set 572 of metric corrections in addition to those appearing in the divergence of a vector (see 573 an outline of the mathematical justification in appendix B, and a heuristic discussion 574 within the paper after Eqns (9)-(13)). These are the last two terms in the two horizontal 575 momentum equation and the last term in the vertical momentum equation. Using the 576 thin shell approximation and the ice shelf approximation $\tau_{\theta z} \approx 0, \tau_{\phi z} \approx 0$, 577

$$0 = -\frac{1}{r\sin\theta}\partial_{\phi}p + \frac{1}{r\sin\theta}\partial_{\phi}\tau_{\phi\phi} + \frac{1}{r\sin\theta}\partial_{\theta}(\sin\theta\tau_{\theta\phi}) + \frac{\cot\theta}{r}\tau_{\theta\phi}$$
(A9)

$$0 = -\frac{1}{r}\partial_{\theta}p + \frac{1}{r\sin\theta}\partial_{\phi}\tau_{\phi\theta} + \frac{1}{r\sin\theta}\partial_{\theta}(\sin\theta\tau_{\theta\theta}) - \frac{\cot\theta}{r}\tau_{\phi\phi}$$
(A10)

$$0 = -\partial_z p - g\rho_I + \partial_z \tau_{zz} - \frac{\tau_{\theta\theta} + \tau_{\phi\phi}}{r}.$$
(A11)

Next, integrate the two horizontal momentum equations from top to bottom and use the 582 Leibniz rule, and integrate the vertical equation first from top to z and then from top to 583 bottom (all such integrals \int_{b}^{s} are over depth, we drop the dz for brevity) to find, 584

$$0 = \frac{1}{r\sin\theta} \partial_{\phi} \int_{b}^{s} (\tau_{\phi\phi} - p) + \frac{1}{r\sin\theta} \partial_{\theta} \int_{b}^{s} (\sin\theta\tau_{\theta\phi})$$
(A12)
$$- \frac{1}{r\sin\theta} s_{\phi} (\tau_{\phi\phi} - p) \Big|_{s} + \frac{1}{r\sin\theta} b_{\phi} (\tau_{\phi\phi} - p) \Big|_{b}$$

$$-\frac{1}{r\sin\theta}s_{\phi}(\tau_{\phi\phi}-p)\Big|_{s} + \frac{1}{r\sin\theta}b_{\phi}(\tau_{\phi\phi}-p)\Big|_{s} + \frac{1}{r\sin\theta}s_{\phi}(\tau_{\phi\phi}-p)\Big|_{s} + \frac{1}{r}\frac{1}{$$

$$0 = -\frac{1}{r}\partial_{\theta}\int_{b}^{s} p + \frac{1}{r\sin\theta}\partial_{\phi}\int_{b}^{s} \tau_{\phi\theta} + \frac{1}{r\sin\theta}\partial_{\theta}\int_{b}^{s} (\sin\theta\tau_{\theta\theta})$$

$$+\frac{1}{r}s_{\theta}p(s) - \frac{1}{r}b_{\theta}p(b)$$

$$-\frac{-r}{r}s_{\theta}\tau_{\theta\theta}(s) + \frac{-r}{r}b_{\theta}\tau_{\theta\theta}(b) - \frac{r}{r}\int_{b}\tau_{\phi\phi}$$

592
592
593
594

$$0 = \int_{b} \left(-(p(s) - p) - g\rho_{I}(s - z) + \tau_{zz}(s) - \tau_{zz}(z) \right)$$

$$-\frac{1}{r} \int_{b}^{s} \int_{z}^{s} (\tau_{\theta\theta} + \tau_{\phi\phi}).$$

579

594

X - 30 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

Using the top and bottom boundary conditions (A4) as well as that $trace(\tau_{ij}) = 0$, 595

$$0 = \frac{1}{r\sin\theta}\partial_{\phi}\int_{b}^{s}(\tau_{\phi\phi} - p) + \frac{1}{r\sin\theta}\partial_{\theta}\int_{b}^{s}(\sin\theta\tau_{\theta\phi}) - \frac{1}{r\sin\theta}b_{\phi}g\rho_{w}\mu h \qquad (A13)$$

$$+ \frac{\cot\theta}{r}\int_{a}^{s}\tau_{\theta\phi}$$

597

$$0 = -\frac{1}{r}\partial_{\theta}\int_{b}^{s} p + \frac{1}{r\sin\theta}\partial_{\phi}\int_{b}^{s} \tau_{\phi\theta} + \frac{1}{r\sin\theta}\partial_{\theta}\int_{b}^{s} (\sin\theta\tau_{\theta\theta}) - \frac{1}{r}b_{\theta}g\rho_{w}\mu h$$

$$\begin{array}{ccc} & & & -\frac{1}{r} \int_{b}^{s} \tau_{\phi\phi} \\ & & & -\int^{s} p = -q\rho_{I} \frac{1}{r} h^{2} + \int^{s} \left(\tau_{\phi\phi} + \tau_{\theta\theta} \right)$$

$$\int_{b}^{600} - \int_{b}^{s} p = -g\rho_{I}\frac{1}{2}h^{2} + \int_{b}^{s} \left(\tau_{\phi\phi} + \tau_{\theta\theta}\right) - \frac{1}{r}\int_{b}^{s}\int_{z}^{s} (\tau_{\theta\theta} + \tau_{\phi\phi})$$

Neglecting the $\mathcal{O}(h/r)$ terms in the third equation and substituting the remaining terms 602 in the first two using h = s - b and $s = (1 - \mu)h$, 603

$$0 = \frac{1}{r\sin\theta} \partial_{\phi} \int_{b}^{s} (2\tau_{\phi\phi} + \tau_{\theta\theta}) + \frac{1}{r\sin\theta} \partial_{\theta} \int_{b}^{s} (\sin\theta\tau_{\theta\phi}) + \frac{\cot\theta}{r} \int_{b}^{s} \tau_{\theta\phi} - \frac{1}{r\sin\theta} g\rho_{I}(1-\mu)hh_{\phi}$$

$$(A14)$$

$$(A14)$$

$$0 = \frac{1}{r\sin\theta} \partial_{\phi} \int_{b}^{s} \tau_{\phi\theta} + \frac{1}{r\sin\theta} \partial_{\theta} \int_{b}^{s} \sin\theta\tau_{\theta\theta} + \frac{1}{r} \partial_{\theta} \int_{b}^{s} (\tau_{\theta\theta} + \tau_{\phi\phi}) - \frac{\cot\theta}{r} \int_{b}^{s} \tau_{\phi\phi} - \frac{1}{r} g\rho_{I}(1-\mu)hh_{\theta}.$$

Using Glen's flow law to express the stress components in terms of the strain rates and 607 therefore velocity components, 608

$$0 = \frac{1}{\sin\theta} \partial_{\phi} \Big[B (2 \frac{1}{\sin\theta} (\partial_{\phi} u + v \cos\theta) + \partial_{\theta} v) \Big]$$

$$+ \frac{1}{\sin\theta} \partial_{\theta} \Big[B \frac{1}{2} (\partial_{\phi} v + \sin^2\theta \partial_{\theta} (u/\sin\theta)) \Big]$$
(A15)

$$+\cot\theta B\frac{1}{2}\left(\frac{1}{\sin\theta}\partial_{\phi}v + \sin\theta\partial_{\theta}(u/\sin\theta)\right) - \frac{1}{\sin\theta}g\rho_{I}(1-\mu)hh_{\phi}$$

$$0 = \frac{1}{\sin\theta} \partial_{\phi} \left[B \frac{1}{2} \left(\frac{1}{\sin\theta} \partial_{\phi} v + \sin\theta \partial_{\theta} (u/\sin\theta) \right) \right] + \left[\frac{1}{\sin\theta} \partial_{\theta} (B \sin\theta \partial_{\theta} v) + \partial_{\theta} \left(B \frac{1}{\sin\theta} \partial_{\theta} (v \sin\theta) \right) \right] + \partial_{\theta} \left(B \frac{1}{\sin\theta} \partial_{\phi} u \right)$$

⁶¹⁴
$$-\cot\theta \frac{1}{\sin\theta} B\left(\partial_{\phi} u + v\cos\theta\right) - g\rho_{I}(1-\mu)hh_{\theta}$$
⁶¹⁵
$$B = \frac{1}{r}h\langle A(T)^{-\frac{1}{3}}\rangle\dot{\epsilon}^{\frac{1}{3}-1}$$

$$\dot{\epsilon}^2 = \frac{1}{2} \left(\dot{\epsilon}^2_{\phi\phi} + \dot{\epsilon}^2_{\theta\theta} + (\dot{\epsilon}_{\phi\phi} + \dot{\epsilon}_{\theta\theta})^2 + 2\dot{\epsilon}^2_{\phi\theta} \right)$$

$$h_t + \frac{1}{r\sin\theta}\partial_{\phi}(uh) + \frac{1}{r\sin\theta}\partial_{\theta}(\sin\theta vh) = \kappa\nabla^2 h + S(\phi,\theta).$$

where $\langle \rangle$ denotes an average over the vertical dimension [see Goodman and Pierrehumbert, 619 2003]. These final equations appear in the text of the paper itself as equations (4)-(8). 620

Appendix B: Divergence of a tensor

Write the divergence operator as 621

$$\nabla \cdot = \hat{\mathbf{e}}_{\phi} \frac{1}{r \sin \theta} \partial_{\phi} + \hat{\mathbf{e}}_{\theta} \frac{1}{r} \partial_{\theta} + \hat{\mathbf{e}}_{r} \partial_{r}, \tag{B1}$$

and note that the unit vectors in spherical coordinates are not constants, such that, for 624 example, $\partial_{\theta} \hat{\mathbf{e}}_{\theta} = -\hat{\mathbf{e}}_r$ [Greenberg, 1998]. Applying the above divergence to a vector \mathbf{v} , 625

$$\nabla \cdot \mathbf{v} = (\hat{\mathbf{e}}_{\phi} \frac{1}{r \sin \theta} \partial_{\phi} + \hat{\mathbf{e}}_{\theta} \frac{1}{r} \partial_{\theta} + \hat{\mathbf{e}}_{r} \partial_{r}) \cdot (\hat{\mathbf{e}}_{\phi} u + \hat{\mathbf{e}}_{\theta} v + \hat{\mathbf{e}}_{r} w)$$
(B2)

we find that the derivatives of the unit vectors introduce a set of correction terms due 628 to the non-Cartesian coordinates. To derive the divergence of a tensor (which yields a 629 DRAFT March 12, 2012, 6:36pm DRAFT X - 32 TZIPERMAN ET AL.: CONTINENTS AND SNOWBALL ICE FLOW

⁶³⁰ vector), write it as

$$\nabla \cdot \boldsymbol{\tau} = (\hat{\mathbf{e}}_{\phi} \frac{1}{r \sin \theta} \partial_{\phi} + \hat{\mathbf{e}}_{\theta} \frac{1}{r} \partial_{\theta} + \hat{\mathbf{e}}_{r} \partial_{r}) \cdot (\hat{\mathbf{e}}_{\phi} \otimes \hat{\mathbf{e}}_{\phi} \tau_{\phi\phi} + \hat{\mathbf{e}}_{\phi} \otimes \hat{\mathbf{e}}_{\theta} \tau_{\phi\theta} + \dots)$$
(B3)

where $\hat{\mathbf{e}}_{\phi} \otimes \hat{\mathbf{e}}_{\theta}$, for example, is a tensor whose only nonzero element is at the $(\phi, \theta) =$ (1, 2) position. Using the expressions for the derivatives of unit vectors we find that the derivatives now include those of the tensor elements (e.g., $\tau_{\phi\theta}$), as well as the derivatives of both unit vectors multiplying each tensor element. We therefore expect two correction terms due to the derivatives of the unit vectors, rather than just one in the case of the divergence of a vector. This leads to the additional terms in the momentum equation discussed in the text.

Acknowledgments. We thank Adam Campbell and two anonymous referees for their most constructive and helpful reviews; thanks to Adam Campbell, Dawei Li and Ray Pierrehumbert for comments on an earlier draft. This study was supported by the NSF P2C2 climate dynamics program, grant ATM-0902844 (ET and YA). ET thanks the Weizmann Institute for its hospitality during parts of this work.

Figure 1. Steady state results of the 1d model (equations 9-13). Left panels: "warm" (experiment 3 in Table 1), right: "cold" case, experiment 4. Upper: ice thickness and meridional velocity as function of latitude. Middle: specified surface temperature. Lower: terms in the continuity equation (13); ("rhs" in the legend denotes the sum of the advection and diffusion terms, which should exactly balance the source S in a steady state).

Figure 2. Upper: steady state results of the 2d nonlinear model for ice thickness (in meters, shown by color contours), and ice velocity field (arrows, m/year, only every fourth velocity vector is drawn). Results are shown for a continental configuration motivated by a 630 Myr reconstruction, based on experiments 9 (warm, left panels) and 10 (cold, right panels), see Table 1. Lower: \log_{10} of the corresponding effective viscosity given by equation (14). Axes indicate degrees longitude and latitude.

March 12, 2012, 6:36pm

Figure 3. A nondimensional Peclet-like ratio of the temperature time rate of change due to horizontal advection vs due to vertical diffusion (eqn 15). Axes indicate degrees longitude and latitude.

Experiment	model	T_{surf}	land	Fig
3	1d	warm	-	1
4	1d	cold	-	1
5	2d	warm	-	-
7	2d	warm	$630 \mathrm{Myr}$	-
8	2d	cold	$630 \mathrm{Myr}$	-
9	2d X2	warm	$630 \mathrm{Myr}$	2
10	2d X2	cold	630Myr	2

Table 1. List of model experiments. X2 means resolution of 176 grid points, otherwise 89 points are used. "Warm" refers to the prescribed surface temperature seen in the middle left panel of Fig. 1, while "cold" refers to that shown in the middle right panel.
