ABSTRACT

Aims. To improve the parameters of the HD 17156 system (peculiar due to the eccentric and long orbital period of its transiting planet) and constrain the presence of stellar companions.

Methods. Photometric data were acquired for 4 transits, and high precision radial velocity measurements were simultaneously acquired with SARG@TNG for one transit. The template spectra of HD 17156 was used to derive effective temperature, gravity, and metallicity. A fit of the photometric and spectroscopic data was performed to measure the stellar and planetary radii, and the spin-orbit alignment. Planet orbital elements and ephemerides were derived from the fit. Near infrared adaptive optic images was acquired with ADOPT@TNG.

Results. We have found that the star has a radius of $R_\ast = 1.44 \pm 0.03 R_\odot$ and the planet $R_p = 1.02 \pm 0.08 R_\oplus$. The transit ephemeris is $T_c = 2454756.73134 \pm 0.00200 + N \times 21.21663 \pm 0.00045$ BJD. The analysis of the Rossiter-McLaughlin effect shows that the system is spin orbit aligned with an angle $\lambda = 4.8^\circ \pm 5.3^\circ$. The analysis of high resolution images has not revealed any stellar companion with projected separation between 150 and 1000 AU from HD 17156.

Key words. stars: individual: HD 17156 – binaries: eclipsing – planetary systems – techniques: spectroscopic, photometric

1. Introduction

The discovery of transiting extrasolar planets (TESP) is of special relevance for the study and characterization of planetary systems. The combination of photometric and radial velocity measurements allows to measure directly the mass and radius of an exoplanet, and hence its density, which is the velocity measurements allows to measure directly the mass and radius of an exoplanet, and hence its density, which is the primary constraint on a planet’s bulk composition. Dedicated follow-up observations of TESP during primary transit and secondary eclipse at visible as well as infrared wavelengths allow direct measurements of planetary emission and absorption (e.g., Charbonneau et al. 2007, and references therein). Transmission spectroscopy during primary eclipse in recent years has been successful in characterizing the atmospheric chemistry of several Hot Jupiters (e.g., Charbonneau et al. 2002 and Tinetti et al. 2007). Infrared measurements gathered at a variety of orbital phases, including secondary eclipse, have permitted the characterization of the longitudinal temperature profiles of nearby TESP. The quickly increasing amount of high-quality data obtained for TESP has provided the first crucial constraints on theoretical models describing the physical structure and the atmospheres of gas and ice exoplanets. The detailed characterization of TESP ultimately is of special relevance to test several proposed formation and orbital evolution mechanisms of close-in planets.

The planet HD 17156b, detected by Fischer et al. (2007) (hereinafter F07) using the radial velocity method, was shown to transit in front of its parent star by Barbieri et al. (2007). Additional photometric measurements were presented in follow-up papers by Gillon et al. (2008), Narita et al. (2008), Irwin et al. (2008), Winn et al. (2008). This planet is unique among the known transiting systems in that its period (21.2 days) is more than 5 times longer than the average period for this sample, and it has the largest eccentricity ($e = 0.67$).

Schlesinger (1910), Rossiter (1924) and McLaughlin (1924) showed that a transiting object, like a stellar companion, produces a distortion in the stellar line profiles due to the partial eclipse of the rotating stellar surface during the event, and thus

1. Introduction

The discovery of transiting extrasolar planets (TESP) is of special relevance for the study and characterization of planetary systems. The combination of photometric and radial velocity measurements allows to measure directly the mass and radius of an exoplanet, and hence its density, which is the primary constraint on a planet’s bulk composition. Dedicated follow-up observations of TESP during primary transit and secondary eclipse at visible as well as infrared wavelengths allow direct measurements of planetary emission and absorption (e.g., Charbonneau et al. (2007), and references therein). Transmission spectroscopy during primary eclipse in recent years has been successful in characterizing the atmospheric chemistry of several Hot Jupiters (e.g., Charbonneau et al. (2002) and Tinetti et al. (2007)). Infrared measurements gathered at a variety of orbital phases, including secondary eclipse, have permitted the characterization of the longitudinal temperature profiles of nearby TESP. The quickly increasing amount of high-quality data obtained for TESP has provided the first crucial constraints on theoretical models describing the physical structure and the atmospheres of gas and ice exoplanets. The detailed characterization of TESP ultimately is of special relevance to test several proposed formation and orbital evolution mechanisms of close-in planets.

The planet HD 17156b, detected by Fischer et al. (2007) (hereinafter F07) using the radial velocity method, was shown to transit in front of its parent star by Barbieri et al. (2007). Additional photometric measurements were presented in follow-up papers by Gillon et al. (2008), Narita et al. (2008), Irwin et al. (2008), Winn et al. (2008). This planet is unique among the known transiting systems in that its period (21.2 days) is more than 5 times longer than the average period for this sample, and it has the largest eccentricity ($e = 0.67$).

Schlesinger (1910), Rossiter (1924) and McLaughlin (1924) showed that a transiting object, like a stellar companion, produces a distortion in the stellar line profiles due to the partial eclipse of the rotating stellar surface during the event, and thus
mospheric parameters ($T_{\text{eff}}$, log $g$, and [Fe/H]) with respect to the values reported by F07.

Our methodology follows a standard procedure whose details can be found in several works of the recent past (e.g., Gonzalez & Lambert [1996], Gonzalez et al. [2001], Santos et al. [2004]). We briefly summarize it here. We initially selected a set of relatively weak Fe I and Fe II lines (see, e.g., Sozzetti et al. [2004], and references therein, for details on the line list), and measured equivalent widths (EWs) using the automated software ARES [1] made available to the community by Sousa et al. (2007). The EWs measured with ARES are then fed to the 2002 version of the MOOG spectral synthesis code (Sneden 1973) together with a grid of Kurucz ATLAS plane-parallel stellar model atmospheres (Kurucz, 1993).

The atmospheric parameters of HD 17156 are then derived under the assumption of local thermodynamic equilibrium, using a standard technique of Fe ionization balance (see, e.g., Santos et al. 2004, Sozzetti et al. 2004, and references therein). We obtained $T_{\text{eff}} = 6100 \pm 75$ K, log $g = 4.1 \pm 0.1$, and [Fe/H]$= +0.14 \pm 0.08$, the formal errors on $T_{\text{eff}}$ and log $g$ having been derived using the procedure described in Neuforge-Verheecke & Magain (1997) and Gonzalez & Vanture (1998), while the nominal uncertainty for [Fe/H] corresponds to the scatter obtained from the Fe I lines rather than the formal error of the mean.

We also quantified the sensitivity of our iron abundance determination to variations of $\pm 1\sigma$ with respect to the nominal $T_{\text{eff}}$, and log $g$ values, and found changes in [Fe/H] of at most 0.05 dex, below the adopted uncertainty of 0.08 dex.

With the aim of further testing the accuracy of the $T_{\text{eff}}$ determination above, we have carried out a few additional consistency checks. For example, in Figure 1 we show the comparison of the observed H$_\alpha$ line profile in an archival Keck/HIRES spectrum against four synthetic profiles for solar-metallicity dwarfs ([Fe/H] = 0.0, log $g = 4.5$) from the Kurucz database. As is well-known, the H$_\alpha$ line is very sensitive to changes in $T_{\text{eff}}$, while relatively insensitive to changes in log $g$ and [Fe/H] (see, e.g., Santos et al. 2006, Sozzetti et al. 2007, and references therein), thus this exercise certainly helps to test the accuracy of the spectroscopic $T_{\text{eff}}$ derived above. The results shown in Figure 1, in which a 10 Å region centered on H$_\alpha$ is displayed together with four calculated profiles for different $T_{\text{eff}}$ values, indicate rather good agreement with the estimate reported in Table 2.

3.2. Age

Based on isochrone fitting, F07 reported an age estimate for HD 17156 of $5.7^{+1.3}_{-1.9}$ Gyr, suggesting an old, slightly evolved F8/G0 primary. We performed an independent isochrone fitting using the set of isochrones of Girardi et al. (2000) and the software PARAM described in da Silva et al. (2006) [2]. The input values for PARAM are the parallax, the visual magnitude, [Fe/H] and $T_{\text{eff}}$. We used the parallax from van Leeuwen (2007) and for the metallicity and effective temperature we ran the code twice, once with the values from F07 and once with our estimate. The results of PARAM for the stellar age are 2.4 ±1 and 2.8 ±1 Gyr, for the F07 and our parameters, respectively. These are only marginally compatible with the previous age estimate by F07. The stellar mass and radius are instead fully compatible (see below).

Other indirect age indicators confirm an age of a few Gyr. The low level of Ca II H & K chromospheric activity suggests an age of about 6 Gyr (Fischer et al. 2007). The lack of X-ray emission from ROSAT (Voges et al. 2000) yields an upper limit of log $L_X < 28.7$. This in turn implies an age older than 1.6 Gyr, using the age-X ray emission calibration by Mamajek & Hillenbrand (2008).

To obtain an additional age estimate and to investigate possible chemical peculiarities of HD 17156 with respect to other planet hosts with similar physical properties, we have measured its lithium (Li) abundance.

Figure 2 shows a spectral synthesis of a 10 Å region centered on the Li $\lambda = 6707.8$ Å line in an archival Keck/HIRES spectrum of HD 17156, and using the atmospheric parameters derived from the Fe-line analysis and the line list of Reddy et al. (2002). In the figure, the observed spectrum is compared to three synthetic spectra, each differing only in the assumed Li abundance. We find a best-fit value of log $\epsilon$(Li) $\approx 2.80$ for HD 17156. We then infer a rather old age for the star of $t > 2$ Gyr, based on the average Li abundance curves as a function of effective temperature for clusters of different ages reported by Sestito & Randich (2005).

The measured Li abundance for HD 17156 does not appear peculiar when compared to that of sub-samples of nearby planet hosts with similar $T_{\text{eff}}$ (Israelian et al. 2004, Gonzalez 2008). To further investigate these issues we will present in a future paper a more detailed study of the elemental abundances in HD 17156.

3.3. Stellar mass and radius

F07 provided mass and radius estimate from isochrone interpolations (mass 1.2 ±0.1 M$_\odot$, radius 1.47$^{+0.13}_{-0.07}$ R$_\odot$). Our isochrone fit (see Sect. 3.2) gives 1.21 ±0.03 and 1.19 ±0.03 M$_\odot$ when
assumed $T_{\text{eff}}$ and $[\text{Fe/H}]$ from the F07 and our analysis respectively, and same radius $1.35 \pm 0.08 R_\odot$.

The comparison of the results of the two fits show that they are compatible within error bars, but the best value is slightly different. The origin of these differences is not univocal, and to understand this problematic independent measurements of the star mass and radii are needed.

### 3.3.1. Monte Carlo experiment. Method

For this purpose we adopted an approach based on a Monte Carlo experiment. In each realization we generated a set of observed stellar properties. Using calibrations from the literature we obtained the corresponding values for mass and radius. From the resulting distributions we obtained the most probable values and relative errors for the mass and radius.

In more detail, we created $10^6$ different synthetic systems where we generated Gaussian distributions for the parallax, the $V$ and $K$ magnitudes, and $T_{\text{eff}}$, using as standard deviations their respective error bars. The input parameters and relative their standard deviations are reported in Tab. 2. In the same way, we generated values for the bolometric correction and the bolometric magnitude of the Sun. For each synthetic set obtained this way we calculated the absolute magnitudes, luminosity, radius, mass, density and gravity.

The $V$ magnitude was obtained from Simbad, $K$ magnitude from 2MASS after conversion to the Bessel-Brett system (Carpenter 2001), and the $T_{\text{eff}}$ from our spectroscopic determination. For the parallax we adopted the recently revised Hipparcos value (van Leeuwen 2007), which indicates that HD 17156 lies at 75 pc from the Sun, 3 pc closer than the previous estimate. The bolometric correction was set to B.C. $= -0.03$ (Girardi et al. 2000) while for the solar bolometric magnitude we used the value $M_{\text{bol,\odot}} = 4.77 \pm 0.02$.

The stellar radius was calculated using the $T_{\text{eff}}$-K magnitude relation of Kervella et al. (2004), and using the Stefan-Boltzmann law. The stellar mass was calculated from various mass-luminosity relations (MLR) namely: $i)$ the classical MLR $L \propto M^{1.5}$; $ii)$ the MLR of Malkov (2007) using absolute magnitude and $M$ stellar luminosity; $iii)$ stellar luminosity; $iv)$ the MLR of Henry (2004). Density and gravity were estimated directly from the radius and mass assuming a spherically symmetric star.

### 3.3.2. Monte Carlo experiment. Results

The distribution of absolute magnitudes in $V$ band peaks at 3.7 (Fig. 3 upper left), while the luminosity is peaked at 2.5 $L_\odot$ (Fig. 3 upper right). These values are slightly different from the ones obtained by Fischer et al., and the source of these differences is ascribed only to the difference in the adopted parallax.

The resulting distributions for the radius are shown in Fig. 3 (middle left). The two relations used provide similar results ($R_S \sim 1.4 R_\odot$) for the best value and also the shape of the distributions is very similar. Fischer et al. suggest a slightly larger radius. Also in this case, the difference originates from the change in the adopted parallax.

In Fig. 3 (middle right) we present the mass distributions obtained with the MLRs. Using the relation of Henry (2004) we obtain the highest mass ($M \sim 1.28 M_\odot$). However, we note that this relation was originally derived from parameters of close binary stars. Malkov (2003) demonstrated that this kind of relations do not well describe single stars. In order to avoid this problem we adopted the MLRs of Malkov (2007) obtained on detached main-sequence double-lined eclipsing binaries. These relations are also valid for slightly evolved stars like HD 17156 (almost all the stars used for deriving these relations are also slightly evolved. O. Malkov, private communication). We obtain best values for the mass between $1.2$ and $1.24 M_\odot$, the first obtained using MLR($M_3$) and the second using MLR($L$). The classical MLR ($M \propto L^{1.5}$) provides $M \sim 1.22 M_\odot$. These results are consistent with the values estimated by F07 ($1.2 \pm 0.1 M_\odot$).

Finally, the resulting distributions for the gravity and density are portrayed in the lower panels of Fig. 3. The mean values are $\log g = 4.22$ and $\rho = 0.58$ g cm$^{-3}$.

The results of this experiment show a fairly good agreement with the estimate of $R_S$ based on isochrone fitting (both our and the one by F07). We conclude that the two independent approaches based on isochrone fitting and the use of scaling relations provide consistent results.

In the following we do not adopt a value for the radius, because we want to determine independently its value from the light-curve fits. Moreover, we fix the value of the mass to the value of the weighted mean of our mass estimation (not using the Henry MLR results) $M = 1.24 \pm 0.03 M_\odot$. We summarize in Table 2 all the data relative to this Monte Carlo experiment.

### 3.4. Rotational velocity

F07 derived $v \sin i = 2.6 \pm 0.5$ km/s for HD 17156. Our template spectrum is suitable for an independent measurement of this quantity. We discuss here three different methods adopted for the measurements of $v \sin i$, based on our template spectra.

With the first method we derive $v \sin i$ by the Fast Fourier Transform analysis of the star’s absorption profile (see Fig 4). To determine the $v \sin i$, the observed profile of a stellar absorption line is made symmetric by mirroring one of its halves, with the purpose to reduce the noise of the FFT. A new profile is calculated by the convolution of a macroturbulence profile (Gaussian) and a rotational one, to compare the FFTs of the symmetric and the calculated (model) profiles. The $v \sin i$ value of the rotation profile, is set as variable parameter until the first minimum of the FFT from the calculated profile coincides with the minimum of the FFT from the symmetric one. The value of $v \sin i$ for HD 17156 was determined considering possible values of macroturbulent velocity ($v_{\text{mac}}$) from B-V and $T_{\text{eff}}$ (Valenti & Fischer, 2005), and we obtained a $v \sin i$ ranging from 1.8 to 2.8 km/s.

The second method that we used consists in obtaining the rotational velocity by means of a suitable calibration of the FWHM of the cross-correlation function against the B-V color. This relation was derived for all the stars in the SARG planet search survey, and it was calibrated into vsin $i$ using stars with known rotational velocity from the literature. Using the B-V from the Tycho catalog converted to the Johnson system (B-V=0.632), the resulting vsin $i = 3.2 ± 1$ km/s.

Finally, using MOOG we synthesized a number of isolated Fe I lines in the template spectrum. From these we measured vsin $i = 3.0 ± 0.5$ km/s.

The values obtained with the three methods suggest a range of values for vsin $i$ compatible with the measurement of F07. The measurement of vsin $i$ from the analysis of Rossiter-Mclaughlin effect will be presented in Section 4.5.

3.5. Galactic orbit

The measurements of the absolute radial velocity given in Section 2 together with the revised parallax and proper motion from Hipparcos van Leeuwen (2007), allow one to calculate the space velocity with respect to the Local Standard of Rest and the galactic orbit of HD 17156. Space velocities are calculated following the procedure delineated by Johnson & Soderblom (1987) and Murray (1989), adopting the value of standard solar motion of Dehnen & Binney (1998) (with U positive toward the galactic anticenter). The calculations yield $(U, V, W) = (+0.6, +26.1, -22.8)$ km/s. The galactic orbit of the star is obtained integrating the equations of motion of a massless particle in the potential described by Allen & Santillan (1991). The equations of motion are solved using the RADAU integrator (Everhart, 1985) assuming that the rectangular galactocentric coordinates of the Sun are $(X_S, Y_S, Z_S) = (8.0, 0.0, 0.015)$ kpc, and that the local circular velocity is 220 km s$^{-1}$. We compute 1000 orbits each time varying randomly the initial coordinates and velocity.
The final light-curve for each telescope was corrected for differential airmass and residual systematic effects dividing them by a linear function of time to the region outside the transit. The photometric error on each point of a light-curve was calculated as the rms over an interval of 30 minutes (the timescale of the ingress/egress phase). The typical rms of the OOT lightcurves are reported in Table 3 while the complete photometric dataset will be available in electronic format at CDS.

The whole dataset consists of ~ 7 000 photometric points. We used these data to perform a global analysis of the planetary transit.

For the light curve fitting we used all the lightcurves that we have collected without performing data binning. In Fig 5 we portrayed the light curves used in this study, folded with the best orbital period from the fit. For displaying purposes the combined light-curve of the 15 lightcurves is shown in Fig. 6 This combined light curve was obtained using a bin width of 90 s, the OOT has an rms of 0.0016.

5. System parameters

We performed the analysis of the HD 17156 system in three steps. First, using the radial velocities presented in Table 1 along with other published RV values: F07 (2 datasets: Keck+Subaru), Narita et al. (2008), Cochran et al. (2008) (2 datasets: HET + HST), we have derived a new spectroscopic orbital solution for HD 17156 . A full Keplerian orbit of five parameters: the radial velocity semi-amplitude $K_p$, the time of periastron passage $T_p$, the orbital period $P$, the orbital eccentricity $e$, and the argument of periastron $\omega$ was adjusted to the data. Second, we have carried out a fit to all the lich-curve that we have obtained and also to the Barbieri et al. (2007) datasets using the $e$, and the $\omega$ obtained from the orbital solution. In this scheme, the adjustable parameters are the ratio of the radii $k = R_p/R_\star$, their relative sum $(R_p + R_\star)/\alpha$, the orbital inclination $i$, the midtransit time $T_c$, and the orbital period $P$. The values derived from the light-curve analysis were then used to determine, through the analysis of the Rossiter-McLaughlin, new values of $\sin i$ and of the angle $\alpha$ between the equatorial plane of the star and the orbital plane of the planet.

The modeling of the transit lightcurve and Rossiter-McLaughlin effect was carried out using the analytical formulæ provided by Giménez (2006a) and Giménez (2006b). The mathematical basis for the description of the two effects is the same, i.e. the Kopal (1977) theory of eclipsing binary stars. This
5.1. Orbital radial velocity analysis

In order to derive the stellar spectroscopic orbit using the combined set of radial velocities mentioned above we used only the OOT measurements in all datasets. Observations in the night of the transit are valuable to this goal because of the steep RV slope (about 23 m/s/hr). We use a downhill simplex algorithm to perform the RV fit to the six datasets, including the zero point shifts between the datasets as free parameters. A stellar jitter of 3 m/s was added in quadrature to the observational errors F07.

The best-fit solution has a value of reduced $\chi^2 = 1.13$, and the results are in close agreement with the discovery paper F07 and its subsequent analysis (Irwin et al., 2008). Uncertainties in the best fit parameters were obtained exploring the $\chi^2$ grid with an adequate resolution. The orbital solution and relative parameter uncertainties are presented in Table 4. In Figure 7 we show the phased radial velocity curve with the best-fit model. Using the value of primary mass provided in Section 3.3 and its uncertainty, the resulting minimum mass for the planet is $m \sin i = 3.21 \pm 0.08 \, M_J$, and the semi-major axis is $a = 0.1614 \pm 0.0010 \, AU$.

5.2. Photometric analysis

We used the description of Giménez (2006a) to analyze the lightcurves obtained in Sect. 4.1. In our model we allowed to vary the ratio of the radii, the phase of first contact, the time of transit center and the orbital inclination. We fixed the limb darkening coefficients to the values corresponding to a star with similar temperature and metallicity to HD 17156 from Claret (2000) tables. For the R band the adopted limb darkening coefficients were: $u_+ = u_a + u_b = 0.6323$ and $u_- = u_a - u_b = -0.0655$. The eccentricity, and the longitude of periastron were held fixed to the best fit values obtained from the RV analysis (Sec. 5.1). Errors were estimated using the bootstrap scheme described in (Alonso et al., 2008).

The results of of the analysis of the 15 datasets are collected in Table 4. Using the third Kepler’s law we obtain for the stellar
and planetary radii $R_p = 1.02 \pm 0.08 \, R_J$ and $R_p = 1.02 \pm 0.08 \, R_J$.

The histogram of the residuals of the light curves (Fig. 8) has a gaussian shape with standard deviation of 0.0062.

The results are consistent with previous determinations (Barbieri et al. 2007, Irwin et al. 2008, Narita et al. 2008, Gillon et al. 2008), nevertheless the values of inclination and stellar radius show larger deviations with respect to values presented by other authors.

In their analysis (Irwin et al. 2008 and Narita et al. 2008) fixed the stellar radius to the value proposed by F07, while Gillon et al. (2008) obtained directly the radius from their analysis. The origin of the discrepancy on the stellar radius might lie in the different values for the inclination, because its value controls the transit duration and the relative sum of the radii. For confirmation we repeated the fit with only the published light-curve of Gillon et al. (2008) and keeping the limb-darkening coefficients for the B band fixed to $u_a = u_a + u_b = 0.7989$ and $u_a = u_a + u_b = 0.0019$. The results are the following: $k = 0.0729 \pm 0.0031$, $\theta_1 = -0.00316 \pm 0.00023$, $i = 87.9 \pm 0.1$, $T_c = 245438.48372 \pm 0.00053$ BJD, $R_S = 1.44 \pm 0.07 \, R_\odot$ and $R_p = 1.02 \pm 0.07 \, R_J$. These results are very close to the results of our previous fit.

Fig. 5. Mosaic of the differential light curves obtained during transits of HD 17156b, obtained with several telescopes. In each box the horizontal axis is the photometric phase and the vertical axis is the relative flux, along with the best fit model. From left to right column and from top to bottom: T1a=Almenara, T1b=Gasparri and T1c=Lopresti datasets from Barbieri et al. (2007), T2a=OH, T2b=Telast, T2c=Castellani, T2d=Asiago, T2e=Lopresti, T2f=Marchini, T2g=Nicolini, T2h=Papini, T2i=Vallerani. T2a to T2i light-curves were collected on 2007 December 03. T3a=Gary 2007 December 25, T4a=Gregorio 2008 September 25, T5a=Gary 2008 October 2008.

Fig. 7. Upper panel: radial velocities of HD 17156 phased to the best-fit orbital solution. Bottom panel: residuals from the orbital solution.
We note that a transit model that does not take into account the non-zero eccentricity might lead to erroneous results in the orbital inclination and thus also the stellar radius (see, for instance, section 3.2 in Alonso et al. 2008).

5.3. Rossiter-McLaughlin effect analysis

The analysis of the TNG RV data obtained during the transit was performed using the formalism developed by Giménez (2006). We allowed to vary $v \sin i$ and $\lambda$ and we fixed the values of $K$, $P$, $e$, $\omega$, $k$, $i_T$, $\theta_1$ to the best values obtained from RV and photometry analysis and reported in Table 5. Fig. 9 presents the best Gaussian fit overlayed. Bottom panel: residuals of radial velocities of HD 17156 phased to the best-fit orbital solution with the best fitted Rossiter-McLaughlin effect overlayed. Table 5. Results of the Rossiter-McLaughlin modeling of all datasets. (OAO: Narita et al dataset).

HD 17156 was observed with AdOpt@TNG, the adaptive optics module of TNG (Cecconi et al. 2006). The instrument feeds the HgCdTe Hawaii 1024x1024 detector of NICS, the near infrared camera and spectrograph of TNG, providing a field of view of about 44 $\times$ 44 arcsec, with a pixel scale of 0.0437 $''$/pixel. Plate scale and absolute detector orientation were derived in a companion program of follow-up of binary systems with long term radial velocity trends from the SARG planet search (Desidera et al. 2007).

Series of 15 sec images on HD 17156 were acquired on 3, 18 and 23 October 2007 in Bry intermediate-band filter. Images were taken moving the target in different positions on the de-
Fig. 10. Bisector velocity span (BVS) from line bisectors of HD 17156 spectra. Upper panel displays BVS vs. RV. Lower panel shows the line bisectors from all spectra, where the horizontal lines enclose the top and bottom zones considered to compute the BVS.

tector, to allow sky subtraction without the need for additional observations, and each night at three different field orientations to make it easier to disentangle true companions from image artifacts. The target itself was used as reference star for the adaptive optics. Observing conditions were poor on the night of October 3, and rather good on the nights of 18 and 23 October, when we obtained a typical Strehl Ratio of about 0.3.

Data reduction was performed by first correcting for detector cross-talk using dedicated routines and then performing standard image preprocessing (flat fielding, bad pixels and sky background corrections) in the IRAF environment. Individual images taken at a fixed orientation were shifted and coadded.

The successive analysis was optimized for the detection of companions in different separation ranges. At small separations (from about 0.15 to 2 arcsec) we selected the two best combined images taken at different field orientations on 2007 Oct 18. They are shown in Fig. 11. These two sets of images are characterized by similar patterns of optical aberrations, and therefore, considering their difference, most of the patterns cancel out in difference images (Fig. 11), improving significantly the detection limits (angular differential imaging, Marois et al. 2006).

In the differential image, a true companion is expected to show two peaks, one positive and one negative, at the same projected separation from the central star and position angle displaced by 20° (the rotation angle between the two sets of images in our case). For detection at separations larger than about 2 arcsec, we summed all the images after an appropriate rotation, obtaining a deep image over a field of about 10×10 arcsec.

No companion was seen in both the differential image at small separation and in the deep combined image within 10 arcsec. The limit for detection was fixed at peak intensities 5 times larger than the dispersion over annuli at different radial separation. The results, both for the differential image and the deep composite image are shown in Fig. 12.

The contrast limits derived above were transformed into limits on companion masses using the mass-luminosity relation by Delfosse et al. (2000), and projected separation in arcsec to AU using the Hipparcos distance to the star (Fig. 13). A main-sequence companion can be excluded at a projected separation between about 150 and 1000 AU (the limit of image size). At such separations only brown-dwarf or white-dwarf companions are compatible with our detection limits. At smaller separation, detectability worsens quickly, and only stars with mass larger than about 0.4 M⊙ can be excluded at projected separations closer than ~ 50 AU.
calibration (Tab. 2). Gillon et al. (2008) obtained a radius of 1.63 ± 0.2 $R_\odot$, which is only marginally compatible with our estimate 1.44 ± 0.08 $R_\odot$. On the one hand, to explain such a large stellar radius and the observed visual magnitude, it would be necessary to add ~ 0.3 mag of interstellar absorption, that at the distance of HD 17156 is not realistic (suggesting a mean extinction of 4 mag/kpc) because HD 17156 is located well inside of the Local Bubble, where no strong absorption is present, and the maximum expected absorption is few hundreds of mag. On the other hand, also the comparison of the Gillon et al. (2008) radius estimate with stellar models does not appear satisfactory: it is not possible to find a model with a radius that agrees with the observed temperature and metallicity of HD 17156. We conclude that the determination of the stellar radius, and by inference planetary radius, Gillon et al. (2008) is overestimated by 15%.

For a planet of 3M$_J$ and an age of ~ 2 Gyr, theoretical models of planet evolution (Baraffe et al. 2008) predict a radius ranging between 0.9 and 1.1R$_J$ as a function of chemical composition of the planet. Our determination of the radius of HD 17156b is $R_p = 1.02 \pm 0.08$ R$_J$. This is in excellent agreement theoretical expectations. Thus, the strong tidal heating effects on the planet do not appear to contribute to significantly inflate its radius.

Fig. 12. Detectability limits for companions of difference magnitude around HD 17156 as a function of the projected separation in arcsec. Continuous line: limits on the difference image. Dotted line: limits on the composite deep image.

Fig. 13. Detectability limits for stellar companions around HD 17156 as a function of the projected separation in AU. Continuous line: limits on the difference image dotted line: limits on the composite deep image.

The residuals from the radial velocity orbital solution do not suggest the occurrence of long term trends. This places further constraints on the binarity of the target. However, the timespan is rather short, and the continuation of the radial velocity monitoring is mandatory for a more complete view.

The available astrometric data from Hipparcos does not show evidence for stellar companions either (no astrometric acceleration within the timespan of the Hipparcos observations and no significant differences between

7. Summary and Discussion

In this paper, we studied the characteristics of HD 17156 and its transiting planets. Stellar parameters (mass, radius, metallicity) agree quite well with the previous study by F07.

Our measurement of the stellar radius of HD 17156 obtained through the analysis of the transit light-curve is the same as the one obtained using the Stefan-Boltzmann law or the Kervella calibration (Tab. 2). Gillon et al. (2008) obtained a radius of 1.63

Therefore HD 17156 joins most of the other exoplanet systems with available measurements of the Rossiter-McLaughlin effect in being compatible with coplanarity. The only possible exception is represented by the XO-3 system, for which Hebrard et al. (2008) found indications for a large departure from coplanarity (~ 70°). However, as acknowledged by the authors, this result should be taken as preliminary, because of the possibility of unrecognized systematic errors for observations taken at large airmass and with significant moonlight contamination.

Our result confirms that large deviations from coplanarity between stellar spin and planet orbit axes are at most rather rare. Such a rarity had already been established at a high confidence level for the “classical” Hot Jupiters in short-period circular orbits. For massive eccentric planets the situation is less clear: HD 147506b ($M = 8.6$ M$_J$, $P = 5.6$ days, $e = 0.52$) and HD 17156 ($M = 3.2$ M$_J$, $P = 21$ days, $e = 0.67$) have projected inclinations below 10° while the possible detection of spin-orbit misalignment in the XO-3 system ($M = 12.5$ M$_J$, $P = 3.2$ days, $e = 0.29$) still awaits confirmation as discussed above.
The results of the spin-orbit alignment measurements for the HD 17156 system can be compared with the prediction of the planet scattering models. A range of alignments can be the outcome of planet-planet scattering (Marzari & Weidenschilling, 2002). Therefore, our indication for coplanarity does not exclude planet-planet scattering in the HD 17156 system. A larger number of transiting planets with significant eccentricities have to be discovered and characterized to get more conclusive inferences. We also searched for stellar companions using adaptive optics, to test the hypothesis of Kozai mechanism to explain the large eccentricity of HD 17156 b. We did not detect companions within 1000 AU, and our detection limits allowed us to exclude main sequence companions with projected separations from about 150 to 1000 AU. This result makes unlikely the occurrence of a companion inducing Kozai eccentricity oscillations on the planet, but this possibility cannot be yet completely rule out (companions at small projected separation and faint white dwarfs and brown dwarfs companion still possible). Continuation of radial velocity and photometric monitoring will allow a more complete view on the existence of additional companions at small separations.
