Abstract

It has been estimated that up to 30% of detectable polyps in patients regress spontaneously. One major challenge in the evaluation of effective therapy of cancer is the readout for tumor regression and favorable biological response to therapy. Inducible near infra-red (NIR) fluorescent probes were utilized to visualize intestinal polyps of mice hemizygous for a novel truncation of the Adenomatous Polyposis coli (APC) gene. Laser Scanning Confocal Microscopy in live mice allowed visualization of cathepsin activity in richly vascularized benign dysplastic lesions. Using biotinylated suicide inhibitors we quantified increased activities of the Cathepsin B & Z in the polyps. More than ½ of the probe signal was localized in CD11b+Gr1+ myeloid derived suppressor cells (MDSC) and CD11b-F4/80+ macrophages infiltrating the lesions. Polyposis was attenuated through genetic ablation of cathepsin B, and suppressed by neutralization of TNFα in mice. In both cases, diminished probe signal was accounted for by loss of MDSC. Thus, in vivo NIR imaging of focal cathepsin activity reveals inflammatory reactions etiologically linked with cancer progression and is a suitable approach for monitoring response to therapy.

Introduction

Colonic and intestinal adenocarcinomas arise as a direct result of the loss of function of the adenomatous polyposis coli (APC) gene and stabilization of β-catenin. Rodent models of hereditary colon cancer faithfully reproduce the histopathology of familial adenomatous polyposis coli (FAP) [1,2] and provide opportunities for investigating secondary events that modulate genetic predisposition to colon cancer [3]. Accumulating evidence suggests that inflammation has causative roles in carcinogenesis [4]. While chronic inflammation can predispose to DNA damage and carcinogenesis, there is evidence to suggest that inflammation is a necessary component of tumor growth. In line with this notion, treatment of APC defective Min mice [5] with cyclooxygenase-2 (COX2) inhibitors results in a transient suppression of polyposis [6,7], an observation that parallels the response of colon cancer patients to similar treatments [8]. Furthermore, anti-TNFα, or the transfer of CD4+CD25+CD45RBlow regulatory T (Treg) cells, both hinder polyph growth in mice [9]. Together these observations strongly argue in favor of a causative link between inflammatory reactions and genetically induced colon cancer, opening possibilities for monitoring and targeting cancer associated inflammation for diagnostic and therapeutic purposes.

Proteolytic enzymes play essential roles in tumor growth, angiogenesis, and invasion. Cathepsins of the cysteine protease family and in particular cathepsin-B are commonly active in the tumor microenvironment, contributing to the regulation of angiogenesis and invasion during cancer progression [10,11]. We have shown that optical in vivo imaging of cathepsin B activity using near infra-red mechanism-based probe allows for highly sensitive detection of adenomatous polyps in mice with direct reflectance imaging [12,13]. The cathepsin inducible fluorescent probe (ProSense 680) is a composite polymer containing a poly-L-lysine backbone; on which quenched NIR (excitation 675 nm, emission 694 nm) fluorophore and several polyethyleno-glycol side-chains are attached. ProSense 680 is preferentially hydrolyzed by cathepsin B, but it can be activated through proteolysis by other cathepsins and other related proteases [14]. Using this approach, mouse polyps were specifically revealed by reflectance imaging [13,14,15] and by in vivo fluorescence endoscopy [16]. However, the cellular source of signal and biological meaning of the protease activity has remained enigmatic.

Here we used targeted in vivo analysis of cysteine cathepsins with ProSense 680. To investigate how specifically the probe activity demarcates areas of dysplasia and the relevance of probe signal to biological activity within the tumor we used the prototype...
Olympus IV 100 scanning LASER intravital microscope to image intestinal lesions in a new mouse model of hereditary polyposis, APC
\(^{D468}\) mice. We report that probe activation reflects the local density of pro-inflammatory cells infiltrating the lesion and amount of associated active enzyme at the tumor site. Furthermore, using cathepsin B deficient APC
\(^{D468}\) (Ctsb
\(^{-/-}\) ) APC
\(^{D468}\) mice, as well as, anti-inflammatory treatments, we provide evidence for a causative link between protease activity, inflammation and polyp growth. Altogether, the present study shows that NIR imaging of pre-neoplastic lesions using near infra red mechanism-based probes is a viable approach to detect biological activities etiologically connected with progressive tumor growth, and provides opportunities for monitoring biological response to effective therapy.

**Results**

Mouse APC
\(^{D468}\) Model: Morphology and Histopathology of Adenomatous Polyps

A novel model of hereditary polyposis was generated by targeted deletion of exons 11 and 12 of the adenomatous polyposis coli (APC), causing truncation of the gene product at codon 468. The resulting mice (APC
\(^{D468}\) ) were backcrossed to C57BL/6j for at least 12 generations. Adenomatous polyps were found in abundance in the small intestine of the hemizygous APC
\(^{D468}\) mice as early as 5 weeks of age, most frequently in the distal ileum (Fig. S1a&b). Colonic polyps were less frequent and increased with age. Morphologically, the polyps were undifferentiated (Fig. S2a&b), were polyclonal (Fig. S2c), tubovillar (Fig. S2d&e), and were composed of tall hyperchromatic disorderly cells with cigar-shaped nuclei (Fig. S2f).

Closer histological examination revealed a rich infiltrate of hematopoietic cells, including granulocytes, mast cells, plasma cells, and lymphocytes (Fig. 1a–d). Two distinct populations of myeloid cells were significantly increased in the lesions: CD11b
\(^{+}\)GR1
\(^{+}\) (MDSC), and CD11b
\(^{+}\)F4/80
\(^{+}\) macrophages (Fig. 1B&C). The MDSC infiltrate increased with age and tumor load (Fig. 2Aa compare with 2Ab; 2Ba&b), while macrophage density was elevated abruptly and remained high (Fig. 2Ac compare with 2Ad; Bc&d). In contrast, the intestine of ageing wt mice showed little infiltration by MDSC, and had delayed increase in macrophages (Fig. 2B, black bars). As the APC
\(^{D468}\) mice aged, anaemia and systemic inflammation developed contributing to a notable increase in the size of the spleen (Fig. S3a), which was in part accounted for by infiltrating MDSC and macrophages (Fig. S3b&c).

Near infra red mechanism-based probes accurately mark areas of dysplasia

Aged mice showing early signs of cachexia were injected with the ProSense 680 (2 nmoles/mouse) 24 hours before the imaging session. To image angiogenesis we employed the constitutively emitting AngioSense 750 probe and injected the mice just before the imaging session.

Mice were anesthetized, a short loop of the small bowel was surgically exposed and individual polyps together with surrounding tissue as well as healthy bowel tissue were imaged with the prototype Olympus IV 100 scanning LASER intravital microscope. Images were collected using dry x4 and x10 lenses in z-stacks, from the tips of the luminal border towards the submucosa. After spectral separation, three channels, namely 694 nm, 790 nm, and 505–510 nm, were used to collect images from the cathespin inducible ProSense 680 (Fig. 3a&b), the vascularity-contrast agent, AngioSense 750 nm (Fig. 3c&d), and auto-fluorescence (Figure 3e&f) respectively. Images were recorded from the tips of the luminal border towards the submucosa. After spectral separation, three channels, namely 694 nm, 790 nm, and 505–510 nm, were used to collect images from the cathespins in inducible ProSense 680 (Fig. 3a&b), the vascularity-contrast agent, AngioSense 750 nm (Fig. 3c&d), and auto-fluorescence (Figure 3e&f) respectively. Images were recorded from the tips of the luminal border towards the submucosa. After spectral separation, three channels, namely 694 nm, 790 nm, and 505–510 nm, were used to collect images from the cathespins in inducible ProSense 680 (Fig. 3a&b), the vascularity-contrast agent, AngioSense 750 nm (Fig. 3c&d), and auto-fluorescence (Figure 3e&f) respectively. Images were recorded from the tips of the luminal border towards the submucosa. After spectral separation, three channels, namely 694 nm, 790 nm, and 505–510 nm, were used to collect images from the cathespins in inducible ProSense 680 (Fig. 3a&b), the vascularity-contrast agent, AngioSense 750 nm (Fig. 3c&d), and auto-fluorescence (Figure 3e&f) respectively.
fluorophore remains quenched, since its backbone is made with poly-D-lysine. Accordingly, while the ProSense 680 signal was readily visible within microadenoma (Fig S5a) the ProSense control 750 failed to become activated (Fig. S5b; see merged Fig. S5a). In a typical experiment, the ratio of the mean intensities of adjacent healthy tissue this ratio was 2.1 ± 0.01 (p < 0.0001 one tailed t test with Welch correction, n = 168 slices) (Fig. S5d). These observations strongly suggest the specific activation of ProSense-680 through proteolytic cleavage.

To investigate whether the increased signal was due to more activity per cell or a greater number of cells with the same individual activity, we analyzed the volume and total intensity of the ProSense 680+ particles. Their mean volume in the polyp z-stack (120900 ± 104900 μm³, n = 92) was over 28 times that in the healthy intestine (4358 ± 797.5 μm³, n = 91, Fig. 3g). The increase in total intensity of the ProSense-680+ particles was directly proportional to the increase in volume of signal (Fig. 3f; 1/slope = 0.004540 for the APC+680 polyps r² = 1, total number of values 51, and 1/slope = 0.004539 for the healthy intestine r² = 0.9999, total number of values 60), suggesting that the increase in signal intensity was due to an increase in the numbers of cathepsin active cells. In agreement with this conclusion, we found no significant difference in the “specific intensity” (intensity per μm³) of the particles found in APC+680 mice (242.9 ± 0.01 units/μm³), and in wt mice (242.2 ± 0.415 units/μm³). The value between the sets being 0.1233 in the unpaired t test with Welch’s correction (the values of the size of the particles and their intensity were collected from the original 16-bit image). Furthermore, it was obvious that the centers of the ProSense-680+ particles were distributed throughout the acquired slices of z-stacks, and were uniformly larger in volume and therefore brighter by about 2 orders of magnitude in the polyps (1.321±10⁷ ± 8.873±10⁸) as compared to the healthy surrounding tissue (8592 ± 1257) (Fig. 3f; Suppl Video S1). Similar analysis of AngioSense-750 showed that the mean volume of the vessels in polyps was nearly 2.5 times higher (11270 ± 3207 μm³, n = 101) than the mean volume of the vessels in the normal intestine tissue (4538 ± 798 μm³, n = 81, Fig. 3h). Thus, increased vessel volume provides an independent means of visualizing early dysplasia, in accordance with published literature that links cathepsin activity with neovascularization [11,19,20].

ProSense 680 is activated by MDSC and macrophages

To reveal the cellular source of cathepsin activity, APC+468 mice were stained in vivo by injecting iv ProSense-680 24 hours prior to being sacrificed. The entire gut was then excised, washed, fixed and embedded in OCT and frozen for histology and immunofluorescence analyses. Immunofluorescence staining revealed overlap of both CD11b (AlexaFluor 488) and Gr1 (AlexaFluor 594) with ProSense-680 signal (Fig. 4a–e), in cells that were dispersed through out the polyp stroma. The Image J “colocalization finder” in conjunction with the “nucleus counter” plug-in was utilized to analyze the fluorescent images. Figure 4d shows the result of the co-localization between the ProSense-680+ (red) and CD11b+ (green) fluorescent images. Co-localized pixels were revealed as white spots, and correspond to the 22/42 CD11b+ cells and 22/36 ProSense 680+ cells. Figure 4e is the outcome of the colocalization analysis between ProSense-680+ (red) and the Gr1+ (green) fluorescent images. Again, co-localized pixels were revealed as white spots, and this time correspond to the 11/45 Gr1+ cells and 11/36 ProSense-680+ cells.

To further characterize cathepsin probe-active cells, total Mono-Nuclear Cells (MNCs) were prepared from intestine of 5-month-old APC+468 mice. These were incubated ex vivo with 0.2 nmoles/ml ProSense-680 for one hour and after cell surface staining subjected to FACS analysis. MDSC and macrophages accounted for over 75% of the ProSense+ MNCs (Fig. 4f&g). Altogether, 11 ± 0.69%, of the living cells (mice n = 6) were stained with the cathepsin activated probe, of which 3.4 ± 0.6 were MDSC and 5.0 ± 0.34% macrophages (Fig. 4i). For control, the MNCs were incubated with 50 μg/ml JPM-565 that is a general cathepsin inhibitor in RPMI 1640 for an hour at 37°C in the presence of 5% CO₂ and then stained with 0.2 nmoles/ml ProSense 680. This resulted in a marked reduction in the intensity...
of staining of CD11b+ cells by Prosense 680 (Fig. S6a). In a typical experiment the frequency of ProSense 680+ cells was reduced from 3.49% to 1.59% (Fig. S6b). This result indicates that cathepsin activity was responsible for the ex vivo staining of myeloid cells by Prosense 680.

Cathepsin activity reports focal inflammatory reactions in dysplasia

To relate the signal to cathepsin activity, we quantified the amounts of active cysteine proteases of the cathepsin family in the polyps as compared to healthy surrounding tissue, and control healthy intestines. To quantify specific protease activity, we used DC-G-04, a biotinylated derivative of the non-specific cathepsin inhibitor JPM-565 that interacts with the active site of cysteine cathepsins [21,22]. Tissue extracts from micro-dissected polyps and from healthy intestine tissues were incubated with DCG-04, and individual cysteine cathepsins were then identified by their relative molecular weights, after separating the extracted proteins by SDS-PAGE. This inhibitor has been used previously to measure active cathepsins B, S, L, and Z (also known as cathepsin X) in cell extracts [21,22]. We used extracts from Cathepsin B deficient mice [23,24] as control. Comparing values from 6 mice per group confirmed significant (P<0.0001) up-regulation of active cathepsin B in polyps (17590±833 OD units) compared with neighboring tissue (7798±993 OD units), or from intestines of healthy age-matched mice (6879±651 OD units)(one tailed t test with Welch correction) (Fig. 5a). Treatment with anti-TNFα caused a significant drop in the levels of polyp specific active cathepsin B (7047±194 OD units; P<0.0001).

Similarly, we detected elevated levels of cathepsin Z in polyps (9886±971 OD) as compared with adjacent tissue (3962±752 OD units; P=0.0005) or with wt intestine tissue (2265±595 OD units; P=0.0005) (one tailed t test with Welch correction). Cathepsin Z measured in the intestine of Ctsb-/- APCΔ468 mice (6364±629 OD units) as compared with wt intestine (2266±595 OD units) (P=0.0179 t test with Welch correction). We were unable to detect cathepsin L and S. Cathepsin L has been reported to be unstable in extract [26].

Live Imaging of Cathepsin B activity Reveals Dynamics of Polyp Growth/Regression

These observations led us to conclude that the ProSense-680 signal was reporting cancer-associated inflammation. We had previously reported that treatment of APCΔ468 mice with anti-TNFα results in suppression of established polyps [27]. To assess
over 75% were either CD11b analyzed for CD11b staining). Green (d, colocalization analysis of ProSense-680 and CD11b staining) and the Gr1 was green (e, colocalization analysis of ProSense-680 and Gr1 staining). The "colocalization finder" plug-in produced images where the colocalized pixels appear white while the ProSense-680 was red (d&v), the CD11b was green (d, colocalization analysis of ProSense-680 and CD11b staining) and the Gr1 was green (e, colocalization analysis of ProSense-680 and Gr1 staining). 

Figures 4 and 5. The cellular source of cathepsin activity. Cryosections of ProSense-680 in vivo stained intestine from APC^A680 mice were stained with antibodies to CD11b (AlexaFluor 488), Gr1 (AlexaFluor 594) and DAPI. The merged images of CD11b with DAPI (a, CD11b green, DAPI gray), Gr1 with DAPI (b, Gr1 red, DAPI gray), and ProSense-680 with DAPI (c, ProSense-680 blue, DAPI gray) were produced with the "RGB gray" plug-in of Image J. The "colocalization finder" plug-in produced images where the colocalized pixels appear white while the ProSense-680 was red (d&v), the CD11b was green (d, colocalization analysis of ProSense-680 and CD11b staining) and the Gr1 was green (e, colocalization analysis of ProSense-680 and Gr1 staining). The live MNCs were gated for ProSense-680 stained intestine from APC^A680 mice. Arrows mark a CD11b^+ Gr1^+ (f, MDSCs) and CD11b^+ F4/80^+ (g, macrophages) cells. Cumulative results of 6 FACS experiments showing % of CD11b^+ Gr1^+ ProSense 680 among total infiltrating MNCs. Note that among the ProSense-680^+ cells (11.0± 0.69% of total MNCs) over 75% were either CD11b^+ Gr1^+ (3.4± 0.6% of total MNCs) or CD11b^+ F4/80^+ (5.0± 0.34% of total MNCs).

doi:10.1371/journal.pone.0002916.g004

Figures 5. Quantification of active cysteine cathepsins using a specific active site directed probe. Polyps from APC^A680 Ctsb^−/−, APC^A680^, and anti-TNFα treated APC^A680^ mice were micro-dissected, pooled, and extracts were incubated with DCG-04 prior to electrophoresis on a 4–12% gradient SDS gel and western blotting; healthy adjacent regions were similarly analyzed. Active Cathepsins were visualized with the use of chemiluminescence reagents. (a) A representative blot. (b) Average Optical Densities (OD) from each band of three independent blots, measured with Image J software; values were normalized with the OD of the β-actin protein, detected using a specific antibody. Open bars: Cathepsin Z, black bars: Cathepsin B. doi:10.1371/journal.pone.0002916.g005

the biological impact of cathepsin-B we compared genetic ablation of cathepsin B [23,24], with treatment of mice with anti-TNFα. Towards this end, we crossed APC^A680^ mice to cathepsin_B deficient mice. Western blot analysis with DCG-04 confirmed that polyps arising in cathepsin-B ablated mice were specifically devoid of cathepsin B activity (Fig. 5a&b), while cathepsin Z was not significantly altered. Interestingly, polyps of anti-TNFα treated mice also showed a selective decrease in cathepsin B, as compared to Z (Fig 5a&b).

Both ablation of cathepsin B and treatment of mice with anti-TNFα significantly reduced polyp density and size. Cathepsin B deficient mice had less polyps (39±2.1 adenoma of Ctsb^−/− APC^A680^ mice n = 8, compared to 94±3.5 adenoma for APC^A680^ n = 16, P<0.0001 unpaired t test with Welsh correction), which had the trend to have smaller size (1.82±0.11 mm diameter for Ctsb^−/− APC^A680^ mice n = 8, compared to 2.047±0.11 mm diameter for APC^A680^ n = 16, P=0.086) (Fig. 6a). Anti-TNFα treated mice also showed reduced numbers (34.3±4.49 adenoma, n = 8, P<0.0001, unpaired t test with Welsh correction) and sizes of polyps (1.516±0.022 mm in diameter, P<0.0001 unpaired t test with Welsh correction, n = 6) (Fig. 6c) as compared to untreated APC^A680^ mice.

FACS analysis revealed that intestines of Ctsb^−/− APC^A680^ mice harbored 40% less ProSense-680^+ MNCs (6.7%±0.69%), as compared to the APC^A680^ (11%±0.69%, P=0.0037, Fig. 6b). This reduction can be attributed to a drop in the levels of MDSCs with ProSense-680 activity (mean frequency 0.56% as compared to 4.46%; P=0.0085, n = 6, unpaired t test with Welsh correction, Fig. 5c). The frequencies of ProSense-680^+ CD11b^+ F4/80^+ cells remain unchanged (mean 5.36% to 5.03% respectively). MDSC density was also markedly reduced in anti-TNFα treated mice.
Discussion

Endoscopic techniques have provided sensitive means of detecting adenomatous polyps that could potentially progress to colon cancer. Thus, endoscopic monitoring of susceptible individuals has made it possible to detect and remove early dysplastic lesions before they become life threatening. To date, visualization of the dysplasia has been limited to detection of anatomical abnormalities, and there is no precedence of live imaging of biological activity that is predictive of tumor growth versus regression. In this study we have shown that cathepsin B activity is an inherent component of cancer-associated inflammation in tumor infiltrating myeloid cells. We have demonstrated that live imaging of this activity is feasible, and provides for accurate demarcation of dysplasia and the associated neo-angiogenesis. Furthermore, we have demonstrated that this mode of imaging reveals dynamics of biological activity that is predictive of tumor progression versus response to therapy.

Cathepsin B activity has been associated with a number of tumors in humans and experimental animals, making it an attractive avenue for the imaging and possible treatment of cancer [10,19,20]. Here we provide evidence that in addition to cathepsin B, another member of the cysteine family of cathepsin Z, Cathepsin B activity has been associated with a number of tumors in humans and experimental animals, making it an attractive avenue for the imaging and possible treatment of cancer [10,19,20]. Here we provide evidence that in addition to cathepsin B, another member of the cysteine family of cathepsin Z is significantly upregulated in adenomatous polyps. Cathepsin activities were focal and readily distinguished the dysplastic lesions from the healthy neighboring tissue. Thus, imaging of this activity

At the top of the image, we can see a figure and a paragraph of text. The figure is labeled Figure 6: Cathepsin B deficiency or anti-TNFα treatment attenuate polyposis. The paragraph discusses the use of cathepsin B in the context of polyp growth and the effects of anti-TNFα therapy. It mentions that cathepsin B’s role in dysplasia is predictive of tumor progression versus response to therapy. The text also notes that endoscopic techniques have provided sensitive means of detecting adenomatous polyps that could potentially progress to colon cancer.

At the bottom of the image, there is another figure labeled Figure 7: Imaging polyps in mice deficient for Cathepsin B or responding to effective anti-TNFα therapy. The figure includes a graph and a paragraph of text that discusses the separation of images from mice treated with anti-TNFα and untreated mice. The text mentions that the group treated with anti-TNFα showed a 2.2 times smaller mean volume compared to the untreated group, indicating a significant attenuation of polyposis. It also notes that there is no precedent for live imaging of biological activity that is predictive of tumor growth versus regression.
using protease sensitive probes allows accurate detection of areas of dysplasia that may be undetectable by visible light imaging, due to size limits or anatomical features.

The source of cathepsin activity in tumors has been in the past debated, with some reports emphasizing that tumor cells are the major source of this activity. Here, we provide evidence based on histology and flow cytometry that clearly reveals tumor infiltrating myeloid lineage cells as the predominant source of this activity. This is a fortunate and useful finding, as cancer-associated inflammation is causatively linked with adenoma growth.

Significantly, our analysis of fluorescent signals detected with in the lesions revealed that the local increase in signal intensity was due to increased numbers of cathepsin active cells rather than higher activity per cell. Furthermore, we could confidently and accurately detect this activity to a depth of at least 75 μm. Thus, the imaged signal was directly reporting the abundance of pro-inflammatory cells within the dysplasia.

We demonstrated that genetic ablation of cathepsin B results in suppression of tumor infiltrating pro-inflammatory cells, notable attenuation of polyposis, and a decrease in the fluorescent signal emanating from the lesions. Ablation of cathepsin B significantly increased the overall levels of active cathepsin Z. Previous reports suggest that cathepsin Z (also called cathepsin X) compensates for the levels of membrane bound catheisin B, and is elevated in cathepsin B knock out mice [25]. Thus, attenuation of probe signal in polyps arising in cathepsin B knock mice suggests that the probe activity was relatively specific for cathepsin B. Furthermore, attenuation of polyposis in these mice suggests a specific requirement for cathepsin B in the progressive growth of polyps.

Surprisingly, cathepsin B deficiency predominantly affected the CD11b+Gr1+ MDSC infiltrate, and did not impact the CD11b+F480+ macrophage component of poly infiltrating leukocytes. Both of these myeloid cell types contributed equally to the local activation of the ProSense 680 probe. Since preferential loss of MDSC correlated with poly attenuation, we conclude that these cells were critically contributing to the progressive growth of dysplasia. Furthermore, we conclude that the decrease in cathepsin activated probe signal was largely due to the loss of MDSCs from areas of dysplasia.

The cytokine TNFα is regarded to be at the apex of inflammatory responses, promoting angiogenesis, mobilization of neutrophils and escalation of inflammation [28,29], including cancer associated inflammatory reactions [30]. Treatment of mice with anti-TNFα suppresses pathogen induced inflammatory bowel disease and inflammation triggered cancer [27,31,32]. We therefore postulated that if pro-inflammatory cells were the source of cathepsin activity and played a causative role in polyposis, then suppression of polyposis-associated inflammation should hinder progressive poly growth, and this therapeutic effect should be reflected in a significant down-regulation of cathepsin activity. Treatment of mice with anti-TNFα resulted in a preferential loss of MDSC infiltrating the lesion, in increased apoptosis of the aberrant epithelial cells, and regression of the lesions. Accordingly, cathepsin-B activities as measured by western blot analysis and probe signal were significantly attenuated. Altogether, these observations establish live imaging of cathepsin B activity with sensitive near infrared probes as a highly specific method for detection of biological activity linked with progressive tumor growth.

Tumor associated neo-angiogenesis is considered to be a necessary pathological component of tumor growth and a viable target for therapeutic intervention. Pro-inflammatory cells are a recognized source of angiogenic factors, and suppression of inflammation is therefore expected to impact tumor associated inflammation. It is not known at what stage dysplasia triggers angiogenesis and how the dynamics of infiltrating leukocytes reflect the expansion or regression of blood vessels in the lesion. Here, taking advantage of a constitutively active near infrared probe we have imaged in a living animal the neo-vascularization of early dysplastic lesions by micro-vessels, and revealed the change in architecture of the vasculature entering the lesion. Using different fluorescent excitation and spectral separation of the images we succeeded in simultaneously imaging both angiogenesis and cathepsin B activity in the same tissue and 3-dimensional space. The visualization of the architecture of the lesion was further enhanced by concomitant imaging of auto-fluorescent signals that emanated largely from the tumor mucosa.

We were able to demonstrate that anti-inflammatory regiments such as ablation of cathepsin B or treatment of mice with anti-TNFα impacts the infiltration of dysplastic lesions by the microvasculature, and that loss of the vessels correlates with attenuation or regression of the lesions. Thus, near infrared imaging of blood microvasculature provides an independent means of monitoring progressive dysplasia, and response to effective therapeutic intervention.

In summary, we have shown that live imaging of mechanism-based near infrared probes allow simultaneous detection of independent biological activities that report progressive tumor growth. Our earlier studies have documented the feasibility of application of this mode of imaging to endoscopic monitoring of cancerous lesions. Here, we have provided mechanistic information on the source and biological significance of the signal. All together, we have documented a powerful advance in our visualization of tumor biology dynamics, which allows for sensitive monitoring cancer progression or favorable response to therapy.

Materials and Methods

Microscope and the operational organization

The prototype Olympus IV 100 LASER scanning intravital microscope was used to collect images from living tissues. This microscope has 4 lasers that with the use of a specialized array of filters can excite a wide variety of fluorochrome including the Cy5.5 (max excitation 680 nm, excited in this microscope with the 633 nm LASER, emission 680 nm) and Cy7 (excitation 749 nm, emission 790 nm). For this study the 4× and the 10× dry objectives were used. The emissions were separated in the desired spectrum through a set of mirrors and filters and collected from 3 Photomultipliers (PMT). Olympus FlowView software is used to compensate the channels and collect the FlowView images.

The microscope uses motors controlled by the software for the collection of the z-stacks used in this report. A 37°C table was available for the comfort of the anesthetized animals during operation.

Live imaging probes

To visualize in detail the cathepsin activity and its distribution along the intestine three probes were utilized, the ProSense 680 (ProSense 680), ProSense control 750 and a high molecular weight (250,000 g/molecule) probe linked with fluorochrome that is excited at 750 nm and emits at 790 nm (AngioSense750). ProSense 680 is a composite probe that is based on a poly-lysyne chain on which a number of fluorochrome molecules were linked on the side chain of the lysine moiety, as well as a number of MPEG molecules. The composite probe with the poly-L-lysyne backbone intact does not emit fluorescence because of quenching, but when the backbone is hydrolyzed by cathepsin the fluorochrome emits a strong signal. ProSense control 750 has a poly-D-lysyne backbone that cannot be hydrolysed by cathepsins.
and therefore remains quenched and it is used as probe to visualize the non specific quenched accumulation of fluorescent dyes in areas of high vascularity. AngioSense 750 remains in the vessels during the normal experimentation period and delineates the vessels. The autofluorescent signal (505–510 nm) was used to visualize the outline of the tissue imaged.

Mouse studies

Cathepsin B knock-out mice have been reported before and were a kind gift [23,24]. Throughout the procedures in which animals were injected with the probe, as well as during the imaging session, mice were anesthetized with inhalation of 1.5–2% mixture of isoflurane in oxygen.

Mice were retro-orbitally injected with the ProSense-680 24 hours before the experimental procedure (2 nm/mouse, 150 μl). Ten minutes before the imaging session the mice were injected with 100 μl of the AngioSense-750. According to our observations most of the probe remains in the vessels for at least 1 hour.

Mice were incised and a loop of the intestine was cut along the length and opened to allow imaging in z stacks from the inside out. The mice were constantly monitored for the rate of the respiration and the depth of their anesthesia. The typical imaging session has duration of 60–90 min. throughout the imaging session the mouse is alive and anesthetized.

All animal experiments were approved by the Harvard Medical School Standing Committee on Animals (protocol 04094, Dr K. Khazaie), by the Dana Farber Cancer Institute IACUC (protocol 02033, Dr Khazaie) and the Northwestern University Animal Study Protocol 2007-1284 (Dr Khazaie) for “imaging proteolytic activity in colon cancer”.

Imaging analysis software

The collected z-stacks were in the form of multiple “. tiff” FlowView files and can be seen and split into channels with the USDA plug-in collection of ImageJ open source software. To analyze the particles we used the bundle of plug-in developed by the Bob and John Wright Cell Imaging Facility of the University of Ontario Canada [http://www.ahrresearch.ca/facilities/wcif/findownload.html]. Several other stack plug-ins were utilized.

Statistical analysis

Any values referred to as statistically analyzed are expressed as “mean value±SEM”. We consider a P value between groups to be significant if P<0.05.

For the preparation of Fig. 3i we employed Linear Regression Analysis to correlate the size of the particles with their total intensity. We used unpaired t test with Welch’s correction analysis to correlate the sets of values of intensity per voxel in the particles of the APCΔ468 adenoma and the wt images, for the comparison of the frequencies of the ProSense-680 stained leukocytes (Fig. 6b) and the correlation of the frequencies of the MDSCs ProSense-680+ cells in APCΔ468 and wt MNCs. We employed one sample t test to compare the size of the ProSense-680+ particles of APCΔ468 adenoma with the ProSense-680+ particles in Ctsb−/− APCΔ468 and TNFα treated APCΔ468 polyps because the size of particles was very diverse in all samples (Fig. 7).

For the preparation of Fig. 6a&c we employed Non-Linear Regression Analysis to correlate the size of the polyps with their number assuming that the size distribution is Gaussian. The non-linear regression graph was superimposed with the actual values of the size and the numbers of the polyps in each individual mouse. “Pirism 4” software was used for all these analyses, and the related graphs.

Immunofluorescence analysis

Mice were stained in vivo for 24 hours with 2 nm ProSense-680. The following day were sacrificed and the fillet-opened intestine was rolled and frozen in OCT. Cryosections were prepared (15 μm) and fixed in aceton (-20°C, 15 min), rehydrated in PBS and incubated with the primary antibodies (biotinylated anti-CD11b, 1:75, and purified rat anti-Gr1, 1:75) antibodies for one hour. The slides were washed in PBS (3 x 3 min each) and incubated with the secondary antibodies (streptavidin AlexaFluor 594, and anti-rat IgG AlexaFluor 488, 1:75 each). After an hour the sections were washed with PBS and mounted with antifade mounting solution that contains DAPI. A specific filter was utilized to visualize the Cy5.5 fluorochrome.

Supporting Information

Figure S1 Distribution of adenomas in the APCΔ468 intestine. (a) the number of polyps plotted against their location throughout the length of the small intestine of 3 month-old mouse. (b) Typical distribution of polyps along the length of the small intestine. (c) Number of polyps as a function of age of mice, plotted in three size groups. (d) Number of polyps as a function of age of mice. Found at: doi:10.1371/journal.pone.0002916.s001 (3.76 MB TIF)

Figure S2 Histological properties of APCΔ468 polyps. (a) β-galactosidase staining APCΔ468 adenoma. (b) PAS staining of a 6 μm paraffin section of an APCΔ468 adenoma. The arrow indicates the characteristic purple staining of the mucus inside the goblet cells. (c) X-gal staining of TS4cre APCΔ468 R36R polyp; (d) H&E staining of a jellyroll preparation of an APCΔ468 intestine. Magnification 50×. The arrow indicates a large adenoma. (e) 100× magnification of an area of the same section. The arrow indicates a small adenoma and the arrowhead a normal villus. (f) 400× magnification of the area surrounded with the white rectangular in (e). The arrow indicates an adenoma. Found at: doi:10.1371/journal.pone.0002916.s002 (3.95 MB TIF)

Figure S3 Systemic inflammation in the APCΔ468 mice. (a) Increase in the weight of the spleen as the mice age (blue dots) as compared to the wt spleen weight (red dots) (P = 0.0003). The CD11b+Gr1+ (b) and the CD11b+F4/80+ (c) cell numbers in the spleen of the APCΔ468(open bars) and the wt (black bars) mice. Found at: doi:10.1371/journal.pone.0002916.s003 (0.47 MB TIF)

Figure S4 Autofluorescence intensity of the APCΔ468 adenoma. The distribution of the auto fluorescence alongside the z-stack. APCΔ468 adenoma shown in Fig. 3f (black squares) as compared to the wt equivalent shown in Fig. 3e (open triangles). Found at: doi:10.1371/journal.pone.0002916.s004 (0.30 MB TIF)

Figure S5 Cathepsin activity is required for unquenched ProSense 680 signal in the APCΔ468 adenoma. APCΔ468 mice were stained a day before the imaging session with 2 nmol/mouse of ProSense-680 and ProSense control 750. Stacks of 168 (1 μm/slice) slices were collected using the Olympus IV100, the UplanApo ×4 and ×2.5 electronic zoom using the channels for ProSense 680 and ProSense control 750. a. merge of the two channels of the160th slice; b. the ProSense 680 image of the 160th slice; c. the ProSense control 750; d. the ratio of the ProSense 680 to the ProSense 750 signal. The mean intensity of the adenoma Region Of Interest (ROI, left rectangular) and the healthy surrounding ROI (right rectangular) was measured for the both channels in all 168 slices. The bar diagram shows that the this ratio is 49±1.4 for the adenoma ROI and 2.1±0.01 for the healthy. The sets of values are statistically significant (P<0.0001, t test with Welch correction). Found at: doi:10.1371/journal.pone.0002916.s005 (1.06 MB TIF)
Figure S6  The use of JPM-565 inhibits the ex vivo staining of the MNCs with ProSense 680. Isolated APCs MNCs were pretreated with 50 μg/ml of JPM-565 in RPMI 1640 for an hour in 37°C and 5% CO2. The positive control remained in the incubator treated with the carrier of the JPM-565. The cell suspension was then stained with 0.2 amoles ProSense 680. The stained cells were stained with PE anti CD11b antibody and DAPI to detect the dead cells. a. represents the flow cytometry of the ProSense 680+ CD11b+ cells untreated with JPM-565 and b. the treated equivalent.
