A Complete Problem for Statistical Zero Knowledge*

Amit Sahai†  Salil Vadhan‡

October 14, 2002

Abstract
We present the first complete problem for SZK, the class of promise problems possessing statistical zero-knowledge proofs (against an honest verifier). The problem, called Statistical Difference, is to decide whether two efficiently samplable distributions are either statistically close or far apart. This gives a new characterization of SZK that makes no reference to interaction or zero knowledge.

We propose the use of complete problems to unify and extend the study of statistical zero knowledge. To this end, we examine several consequences of our Completeness Theorem and its proof, such as:

• A way to make every (honest-verifier) statistical zero-knowledge proof very communication efficient, with the prover sending only one bit to the verifier (to achieve soundness error 1/2).

• Simpler proofs of many of the previously known results about statistical zero knowledge, such as the Fortnow and Aiello-Håstad upper bounds on the complexity of SZK and Okamoto’s result that SZK is closed under complement.

• Strong closure properties of SZK which amount to constructing statistical zero-knowledge proofs for complex assertions built out of simpler assertions already shown to be in SZK.

• New results about the various measures of “knowledge complexity,” including a collapse in the hierarchy corresponding to knowledge complexity in the “hint” sense.

• Algorithms for manipulating the statistical difference between efficiently samplable distributions, including transformations which “polarize” and “reverse” the statistical relationship between a pair of distributions.

---

1 Introduction

A revolution in theoretical computer science occurred when it was discovered that \( \text{NP} \) has complete problems [Coo71, Lev73, Kar72]. Most often, these theorems and other completeness results are viewed as negative statements, as they provide evidence of a problem’s intractability. These same results, viewed as positive statements, enable one to study an entire class of problems by focusing on a single problem. For example, all languages in \( \text{NP} \) were shown to have computational zero-knowledge proofs when such a proof was exhibited for \text{GRAPH 3-COLORABILITY} [GMW91]. Similarly, the result that \( \text{IP} = \text{PSPACE} \) was shown by giving an interactive proof for \text{QUANTIFIED BOOLEAN FORMULA}, which is complete for \text{PSPACE} [LFKN92, Sha92]. More recently, the celebrated PCP theorem characterizing \( \text{NP} \) was proven by designing efficient probabilistically checkable proofs for a specific \( \text{NP} \)-complete language [ALM+98, AS98].

In this paper, we present a complete problem for \( \text{SZK} \), the class of promise problems\(^1\) possessing statistical zero-knowledge proofs (against an honest verifier). This problem provides a new and simple characterization of \( \text{SZK} \) — one which makes no reference to interaction or zero knowledge. We propose the use of complete problems as a tool to unify and extend the study of statistical zero knowledge. To this end, we use our complete problem to both establish a number of new results about \( \text{SZK} \) and easily deduce nearly all previous results about \( \text{SZK} \).

1.1 Statistical zero knowledge

Zero knowledge was introduced in the seminal paper of Goldwasser, Micali, and Rackoff [GMR89] within the context of their new notion of interactive proof systems. Informally, an interactive proof is a protocol in which a computationally unbounded prover \( P \) attempts to convince a probabilistic polynomial-time verifier \( V \) of an assertion, namely that a string \( x \) is a \text{YES} instance of some (promise) problem. The zero knowledge property requires that, during this process, the verifier learns nothing beyond the validity of the assertion being proven. To formalize this seemingly impossible notion, two probability distributions are considered:

1. The interaction of \( P \) and \( V \) from \( V \)'s point of view.
2. The output of a probabilistic polynomial-time machine not interacting with anyone, called the simulator, on input \( x \).

An interactive proof system \((P,V)\) is said to be zero knowledge if, for every \text{YES} instance \( x \), the two distributions above are “alike.” Intuitively, the verifier gains no knowledge by interacting with the prover except that \( x \) is a \text{YES} instance, since it could have run the simulator instead. The specific variants of zero knowledge differ by the interpretation given to “alike.” The most strict interpretation, leading to perfect zero knowledge, requires that the distributions be identical. A slightly relaxed interpretation, leading to statistical zero knowledge (sometimes called almost perfect zero knowledge), requires that the distributions have negligible statistical difference from

\(^1\)A promise problem is a decision problem given by a pair of disjoint sets of strings, corresponding to \text{YES} and \text{NO} instances. In contrast to languages, there may be strings which are neither \text{YES} instances nor \text{NO} instances. A formal definition of promise problems is given in Section 2.1.

Although our complete problem is not a language, it still provides a meaningful characterization of the class of languages possessing statistical zero-knowledge proofs. Moreover, essentially all of the applications of our Completeness Theorem to prove results about the promise class \( \text{SZK} \) also imply the analogous results for the language class. Thus, throughout the paper, all discussion refers to promise problems rather than languages (except where otherwise noted). Section 2.1 contains further elaborates on the issue of promise problems vs. languages.
one another. The most liberal interpretation, leading to computational zero knowledge, requires that samples from the two distributions be indistinguishable by any polynomial-time machine.

In this work, we focus on the class of problems possessing statistical zero-knowledge proof systems, which we denote SZK. We remark that we concentrate on zero-knowledge proofs against an honest verifier, i.e. the verifier that follows the specified protocol. In cryptographic applications, one usually wants the zero-knowledge condition to hold for all (even cheating) verifier strategies. However, subsequent to this work, it has been shown that one can transform any proof system that is statistical zero knowledge against an honest verifier into one that is statistical zero knowledge against all verifiers [GSV98], so restricting our attention to honest verifiers causes no loss of generality.

One reason for interest in SZK is that it contains a number of important computational problems. These include problems not known to be in NP, such as GRAPH NONISOMORPHISM [GMW91] and PERMUTATION GROUP NONISOMORPHISM [Kan89]. It also contains problems with cryptographic application and significance that are believed to be hard on average, such as QUADRATIC RESIDUOUSITY (and its complement) [GMR89], a problem equivalent to the DISCRETE LOGARITHM problem [GK93], and approximate versions of the SHORTEST VECTOR and CLOSEST VECTOR problems in lattices [GG00]. At the same time, the statistical zero knowledge property has several strong consequences. Unlike a computational zero-knowledge protocol, a statistical zero-knowledge protocol typically remains zero knowledge even against a computationally unbounded verifier. In addition, a problem which has a statistical zero-knowledge proof must lie low in the polynomial-time hierarchy. In fact, such a problem cannot be NP-complete unless the polynomial-time hierarchy collapses [For89, AH91, BHZ87]. Because SZK contains problems believed to be hard yet cannot contain NP-complete problems, it holds an intriguing position in complexity theory.

1.2 The complete problem

The promise problem we show to be complete for SZK is STATISTICAL DIFFERENCE. An instance of STATISTICAL DIFFERENCE consists of a pair of probability distributions, specified by circuits which sample from them. Roughly speaking, the problem is to decide whether the distributions defined by the two circuits are statistically close or far apart. (The gap between ‘close’ and ‘far apart’ is what makes it a promise problem and not just a language.) Our main theorem is that STATISTICAL DIFFERENCE is complete for SZK. This Completeness Theorem gives a new characterization of SZK. Informally, it says that the assertions that can be proven in statistical zero knowledge are exactly those that can be cast as deciding whether a pair of efficiently samplable distributions are statistically close or far apart.

The starting point for our proof of the Completeness Theorem is a powerful theorem of Okamoto [oka00], which states that all languages in SZK have public-coin (also known as Arthur-Merlin [BM88]) statistical zero-knowledge proofs. Using the approach pioneered by Fortnow and others [For89, AH91, Ost91], we analyze the simulator of such a proof system and show that statistical properties of the simulator’s output distribution can be used to distinguish between YES and NO instances of the problem in consideration. Our key new observation is that, for a public-coin proof system, these statistical properties can be captured by the statistical difference between efficiently samplable distributions. We thereby conclude that every problem in SZK reduces to STATISTICAL DIFFERENCE.

To show that STATISTICAL DIFFERENCE is in SZK, we exhibit a simple 2-message proof system for it, generalizing the well-known proof systems for QUADRATIC NONRESIDUOUSITY [GMR89] and

\footnote{A rare exception are the results of [BMO90], which yield protocols that are only zero knowledge for polynomial-time verifiers.}
Graph Nonisomorphism [GMW91]. One ingredient in our proof system is a new “Polarization Lemma” for statistical difference, which may be of independent interest. Roughly speaking, this lemma gives an efficient transformation which takes as input a pair of probability distributions (specified by circuits which sample from them) and produces a new pair of distributions such that if the original pair is statistically close (resp., far apart), the new pair is statistically much closer (resp., much further apart).

1.3 Consequences

We propose using complete problems, such as Statistical Difference, to unify and extend the study of SZK. We also use the connection between SZK and statistical properties of sampleable distributions to establish new techniques for manipulating such distributions. The results we obtain along these lines are summarized below.

The relationship between SZK and BPP. Our complete problem illustrates that statistical zero knowledge is a natural generalization of BPP. In the definition of Statistical Difference, the circuits can output strings of any length. If we restrict the circuits to have output of logarithmic length, the resulting problem is easily shown to be complete for BPP.

Efficient SZK proof systems. The zero-knowledge proof system we exhibit for Statistical Difference has many attractive properties (which we describe shortly); by the Completeness Theorem it follows that every problem in SZK also has a proof system with such properties. First, the protocol is very communication efficient — only two messages are exchanged between the prover and verifier, and the prover only sends one bit to the verifier (to achieve soundness error $1/2$). In addition, we will show that when the input is a YES instance, the verifier’s view of the interaction can be simulated by a polynomial-time simulator with exponentially small statistical deviation.

Closure properties. Using the complete problem, we demonstrate that SZK has some very strong closure properties. These can be informally described as asserting the existence of statistical zero-knowledge proofs for complex assertions built out simpler assertions already known to be in SZK. These complex assertions take the form of arbitrary propositional formulae whose atoms are statements about membership in some problem in SZK, and the statistical zero-knowledge proofs we exhibit have complexity which is polynomial in the size of these formulae. These results strengthen earlier ones of De Santis, Di Crescenzo, Persiano, and Yung [DDPY94] and Damgård and Cramer [DC96], which held for monotone formulae and various subclasses of SZK, such as random self-reducible problems.

By the Completeness Theorem, the closure properties we establish are equivalent to the existence of efficient transformations that manipulate the statistical difference between sampleable distributions in various ways. Indeed, it is by exhibiting such transformations that we prove the closure properties of SZK. The transformations we give (and their application to closure properties) are inspired by the techniques of De Santis, Di Crescenzo, Persiano, and Yung [DDPY94].

Simpler proofs of previous results. Many of the previous results about SZK can be deduced as immediate corollaries of our Completeness Theorem and its proof. For example, the result of Okamoto [Oka00] that SZK is closed under complement follows directly from our proof of the Completeness Theorem. Then, using the fact that our proof system for Statistical Difference is a constant-round one, we deduce that $SZK \subseteq AM \cap \text{co-AM}$, as originally proven by Fortnow [For89].
and Aiello and Hästad [AH91]. In addition, the result of Ostrovsky [Ost91] that one-way functions exist if SZK contains a hard-on-average problem follows immediately by combining our Completeness Theorem with a result of Goldreich [Go90] on computational indistinguishability.

**Knowledge complexity.** In addition to introducing zero-knowledge proofs, the conference version of the paper of Goldwasser, Micali, and Rackoff [GMR89] proposed a more general idea of measuring the amount of knowledge leaked in an interactive proof. Goldreich and Petrank [GP99] suggested several definitions of knowledge complexity to accomplish this, and relationships between these various types of knowledge complexity were explored in [GP99, BP92, GOP98, ABV95, PT96]. Loosely speaking, the definitions of (statistical) knowledge complexity measure the “amount of help” a verifier needs to generate a distribution that is statistically close to its real interaction with the prover. There are several ways of formalizing the “amount of help” the verifier needs and each leads to a different notion of knowledge complexity.

Our work on SZK turns out to have consequences for (non-zero) knowledge complexity as well. First, we show that for the weakest of the various measures of knowledge complexity, namely statistical knowledge complexity in the “hint sense”, the corresponding hierarchy collapses by logarithmic additive factors at all levels, and in particular, knowledge complexity \( \log n \) equals statistical zero knowledge. No collapse was previously known for any of the variants of knowledge complexity suggested in [GP99]. Our results are obtained by combining our results on SZK with a general lemma relating knowledge complexity in the hint sense to zero knowledge for promise problems.

As with zero knowledge, perfect knowledge complexity can also be defined. This measures the number of bits of help the verifier needs to simulate the interaction exactly, rather than statistically closely. Using our complete problem for SZK, we improve some results of Aiello, Bellare, and Venkatesan [ABV95] on the perfect knowledge complexity of statistical zero knowledge.

**Reversing statistical difference.** One interesting result that follows from the completeness of Statistical Difference and the closure of SZK under complement is the existence of an efficient mapping which “reverses” statistical difference. That is, for every pair of efficiently samplable distributions, we can construct another pair of efficiently samplable distributions such that when the former are statistically close, the latter are statistically far apart, and when the former are far apart, the latter are close.

This motivated us to search for a more explicit description of such a transformation. By extracting ideas from the work of Okamoto [Oka00] and our proof of the Completeness Theorem, we have obtained such a description (which we give in Section 4.4).

**Weak SZK and expected polynomial-time simulators.** The original definition of SZK in [GMR89] allows the simulator to run in expected polynomial time, whereas we insist on strict polynomial time, following [Go01]. Actually, our proof of the Completeness Theorem shows that the two definitions are equivalent for public-coin proof systems. That is, if a problem possesses a public-coin SZK proof system with an expected polynomial-time simulator, then it also possesses an SZK proof system with a strict polynomial-time simulator (which can be made public coin by [Oka00]). In fact, the equivalence extends to an even weaker definition of SZK, in which it is only required that for every polynomial \( p(n) \), there exists a simulator achieving simulator deviation \( 1/p(n) \).

**Perfect and computational zero knowledge.** Our techniques can also be used to analyze public-coin perfect and computational zero-knowledge proofs. Although we do not obtain com-
plete problems in these cases, we do obtain some novel insights into the corresponding complexity
classes. Specifically, in Section 5.2 we show that every problem possessing a public-coin perfect
zero-knowledge proof (essentially) reduces to a restricted version of Statistical Difference.
We also show that for any problem possessing a public-coin computational zero-knowledge proof,
there exist ensembles of samplable distributions indexed by instances of the problem such that on
YES instances, the distributions are computationally indistinguishable and on NO instances, the
distributions are statistically far apart.

Cheating-verifier zero knowledge. While in this paper we primarily focus on honest-verifier
statistical zero knowledge, there have been a number of works examining “cheating-verifier” statistical
zero knowledge, and in particular relating the honest and cheating-verifier definitions. Some
of these works exhibited transformations from honest-verifier SZK proofs to cheating-verifier ones
under (successively weaker) complexity assumptions [BMO90, OVY93, Oka00], and others gave
unconditional transformations for restricted subclasses of SZK [Dam93, DGOW95]. Finally, subse-
tuent to our paper, it was proven in [GSV98] that honest-verifier and cheating-verifier SZK are the
equal, unconditionally and with no restrictions.

Following the paradigm advocated in [BMO90], we use the above transformations to translate
our results about honest-verifier SZK, namely the Completeness Theorem and its corollaries, to the
cheating-verifier class. In Section 5.4, we precisely state the results thereby obtained for cheating-
verifier statistical zero knowledge.

1.4 Subsequent work

Subsequent to the conference version of this paper [SV97], there have been a number of other
works improving our understanding of SZK, many of which make use of the complete problem
methodology advocated here. As mentioned above, Goldreich, Sahai, and Vadhan [GSV98] show
that honest-verifier statistical zero knowledge equals cheating-verifier statistical zero knowledge.
Goldreich and Vadhan [GV99] use the complete problem methodology to give a simpler proof of
Okamoto’s theorem that private-coin SZK equals public-coin SZK (on which our work relies). In
the process, they exhibit another complete problem for SZK, called Entropy Difference, which
amounts to deciding which of two given distributions (specified by circuits which sample from them)
has noticeably higher entropy than the other. Di Crescenzo, Sakurai, and Yung [DSY00] consider
two variants of (honest-verifier) statistical zero-knowledge proofs, namely “proofs of decision power”
and “proofs of decision”, and exhibit such proof systems for all of SZK. Their construction makes
use of the complete problems for SZK given here and in [GV99] and special properties of their proof
systems. Goldreich, Vadhan, and Wigderson [GKV01] study the complexity of interactive proofs
with low prover-to-verifier communication. Using our complete problem, they show that the class
of problems with interactive proofs in which the prover sends only one bit to the verifier is exactly
SZK (modulo some constraints on the completeness and soundness probabilities).

De Santis, Di Crescenzo, Persiano and Yung [DPY98] extend the use of complete problems to study
“noninteractive” statistical zero knowledge; they exhibit a complete problem for the corre-
sponding complexity class NISZK and use it to prove some general results about the class. Goldreich,
Sahai, and Vadhan [GSV99] exhibit two more complete problems for NISZK. These problems are
natural restrictions of the complete problems for SZK given here and in [GV99], and thus they are
able to use the complete problems to relate SZK and NISZK. Gutfreund and Ben-Or [GB00] examine
weaker models of noninteractive zero knowledge proofs, and, using our complete problem and
reversal mapping, show that every problem in SZK has a noninteractive statistical zero-knowledge

5
proof in one of their models.

Finally, Vadhan [Vad00] examines the blow-up in the prover’s complexity incurred by transformations from private-coin proof systems to public-coin proof systems, such as those in [GS89, Oka00], and shows that this inefficiency is inherent in the fact that the transformations use the original prover and verifier strategies as “black boxes”. In fact, it is shown that any black-box transformation which preserves the prover’s complexity must fail on our proof system for **Statistical Difference**.

Unified presentations of many of the above results, together with the results in this paper, can be found in the Ph.D. theses of the authors [Vad99, Sah00].

## 2 Preliminaries

### 2.1 Promise problems and completeness

The problem we prove to be complete for \( \text{SZK} \) is not a language, but rather a **promise problem** [ESY84]. Formally, a promise problem \( \Pi \) consists of two disjoint sets of strings \( \Pi_Y \) and \( \Pi_N \), where \( \Pi_Y \) is the set of **yes instances** and \( \Pi_N \) is the set of **no instances**. A promise problem \( \Pi \) is associated with the following computational problem: Given an input which is “promised” to lie in \( \Pi_Y \cup \Pi_N \), decide whether it comes from \( \Pi_Y \) or \( \Pi_N \). The **complement** of \( \Pi \) is the promise problem \( \bar{\Pi} \), where \( \bar{\Pi}_Y = \Pi_N \) and \( \bar{\Pi}_N = \Pi_Y \). Note that languages are a special case of promise problems.

We say that promise problem \( \Pi \) **reduces** to promise problem \( \Gamma \) if there is a polynomial-time computable function \( f \) such that

\[
\begin{align*}
x \in \Pi_Y & \Rightarrow f(x) \in \Gamma_Y \\
x \in \Pi_N & \Rightarrow f(x) \in \Gamma_N
\end{align*}
\]

That is, we work with polynomial-time many-one (or Karp) reductions, unless otherwise specified. We say that \( \mathcal{C} \) is **closed under reductions** if \( \Pi \) reduces to \( \Gamma \) and \( \Gamma \in \mathcal{C} \) \( \Rightarrow \Pi \in \mathcal{C} \).

If \( \mathcal{C} \) is a class of promise problems, we say that promise problem \( \Pi \) is **complete** for \( \mathcal{C} \) if \( \Pi \in \mathcal{C} \) and every promise problem in \( \mathcal{C} \) reduces to \( \Pi \).

If \( \mathcal{C} \) is a class of promise problems, the corresponding **language class** \( \mathcal{C}_{\text{lang}} \subset \mathcal{C} \) is the class of languages in \( \mathcal{C} \). It should be noted that \( \mathcal{C} \) and \( \mathcal{C}_{\text{lang}} \) do not always have the same complexity-theoretic properties, particular when allowing reductions that can violate the promise. For example, the promise-problem version of \( \text{NP} \cap \text{co-NP} \) contains a problem which is \( \text{NP} \)-hard with respect to Cook reductions, whereas this does not hold for the language class \( \text{NP} \cap \text{co-NP} \) assuming \( \text{NP} \neq \text{co-NP} \) [ESY84]. (See also [GG98].)

Nevertheless, in this paper the study of a promise class \( \mathcal{C} \) (namely \( \mathcal{C} = \text{SZK} \)) proves to be very useful in understanding the corresponding language class. There are two main reasons for this. First, if \( \mathcal{C} \) is closed under reductions (as we will prove for \( \mathcal{C} = \text{SZK} \)) and \( \Pi \) is complete for \( \mathcal{C} \), then \( \Pi \) also meaningfully characterizes \( \mathcal{C}_{\text{lang}} \) in that \( \mathcal{C}_{\text{lang}} = \{ L : L \text{ reduces to } \Pi \} \). Second, many of our results are of the form “For every problem \( \Pi \in \mathcal{C}, \ldots \)”. Clearly, all such results will also apply to \( \mathcal{C}_{\text{lang}} \) because \( \mathcal{C}_{\text{lang}} \subset \mathcal{C} \).

### 2.2 Probability distributions

If \( X \) is a probability distribution (or random variable), we write \( x \leftarrow X \) to indicate that \( x \) is a sample taken from \( X \). If \( S \) is a set, we write \( x \in_r S \) to indicate that \( x \) is uniformly selected from \( S \).
In this paper, we will consider probability distributions defined both by circuits and by probabilistic algorithms (i.e., Turing machines). If $A$ is a probabilistic algorithm, we use $A(x)$ to denote the output distribution of $A$ on input $x$. A PPT algorithm (for “probabilistic polynomial time”) is a probabilistic algorithm which runs in strict polynomial time. If $C$ is a circuit mapping $m$-bit strings to $n$-bit strings, then choosing an input $u$ uniformly at random from $\{0, 1\}^m$ defines a probability distribution on $\{0, 1\}^n$ given by $C(u)$. For notational convenience, we also denote this probability distribution by $C$. These definitions capture the idea of an “(efficiently) samplable” distribution, as to sample from the distribution one need only run the algorithm or evaluate the circuit.

2.3 The statistical difference metric

For probability distributions (or random variables) $X$ and $Y$ on a discrete set $D$, the statistical difference between $X$ and $Y$ is defined to be

$$\|X - Y\| = \max_{S \subseteq D} |\Pr[X \in S] - \Pr[Y \in S]|. \quad (1)$$

This is often also called the variation distance between $X$ and $Y$. Removing the absolute values in (1) does not change the definition because replacing $S$ by its complement changes the sign (but not magnitude) of $\Pr[X \in S] - \Pr[Y \in S]$. The maximum in (1) can be achieved by taking $S = \{x : \Pr[X = x] > \Pr[Y = x]\}$ (or its complement); this can be seen directly or in the proof of Fact 2.1 below.

There is an equivalent formulation of statistical difference in terms of the $\ell_1$ norm $|\cdot|_1$ that will sometimes be more convenient for us. To every probability distribution $X$ on a discrete set $D$, the mass function of $X$ is a vector in $\mathbb{R}^D$ whose $x$’th coordinate is $\Pr[X = x]$. For the sake of elegance, we also denote this vector by $X$. With this notation, we can state the following well-known fact.

Fact 2.1 $\|X - Y\| = \frac{1}{2} |X - Y|_1$

The proof of this fact and others in this section are deferred to Appendix A. It is immediate from this characterization of statistical difference that it is a metric (as long as we identify random variables that are identically distributed). In particular, it satisfies the Triangle Inequality.

Fact 2.2 (Triangle Inequality) For any probability distributions $X$, $Y$, and $Z$,

$$\|X - Y\| \leq \|X - Z\| + \|Z - Y\|$$

Recall that for any two vectors $v \in \mathbb{R}^n$ and $w \in \mathbb{R}^n$, their tensor product $v \otimes w$ is the vector in $\mathbb{R}^{nm}$, whose $(i, j)$’th component is $v_i w_j$. Now, if we have a pair of random variables $(X, Y)$ (on the same probability space) taking values in $D \times E$, then $X$ is independent from $Y$ iff the mass function of $(X, Y)$ is the tensor product of the mass functions of $X$ and $Y$ (which are elements of $\mathbb{R}^D$ and $\mathbb{R}^E$, respectively). For this reason, if we have random variables $X$ and $Y$ taking values in sets $D$ and $E$, respectively, we write $X \otimes Y$ for the random variable taking values in $D \times E$ which consists of independent samples of $X$ and $Y$. Similarly, $\otimes^k X$ denotes the random variable taking values in $D^k$ consisting of $k$ independent copies of $X$, i.e. $X \otimes X \otimes \cdots \otimes X.$

Now, for any two vectors $v$ and $w$, $|v \otimes w|_1 = |v|_1 \cdot |w|_1$. In addition, for any mass function $X$, $|X|_1 = 1$. These facts enable one to show that the statistical difference behaves well with respect to independent random variables:
Fact 2.3 Suppose $X_1$ and $X_2$ are independent random variables on one probability space and $Y_1$ and $Y_2$ are independent random variables on another probability space. Then,

$$\| (X_1, X_2) - (Y_1, Y_2) \| \leq \| X_1 - Y_1 \| + \| X_2 - Y_2 \|$$

One basic fact about statistical difference is that it cannot be created out of nothing. That is, for any procedure $A$, even if it is randomized, the statistical difference between $A(X)$ and $A(Y)$ is no greater than the statistical difference between $X$ and $Y$. Formally, if $D$ is any set, a randomized procedure on $D$ is a a pair $A = (f, R)$, where $R$ is a probability distribution on some set $E$ and $f$ is a function from $D \times E$ to any set $F$. Think of the distribution $R$ as providing a “random seed” to the procedure $A$. If $X$ is a probability distribution on $D$, then $A(X)$ denotes the probability distribution on $F$ obtained by sampling $X \otimes R$ and applying $f$ to the result. Note that applying a function is a special case of applying a randomized procedure.

Fact 2.4 If $X$ and $Y$ are random variables and $A$ is any randomized procedure, then

$$\| A(X) - A(Y) \| \leq \| X - Y \|$$

The next fact is useful when arguing that the statistical difference between distributions is small.

Fact 2.5 Suppose $X = (X_1, X_2)$ and $Y = (Y_1, Y_2)$ are probability distributions on a set $D \times E$ such that

1. $X_1$ and $Y_1$ are identically distributed, and
2. With probability greater than $(1 - \epsilon)$ over $x \leftarrow X_1$ (equivalently, $x \leftarrow Y_1$),

$$\| X_2 \mid X_1=x - Y_2 \mid Y_1=x \| < \delta$$

(where $B \mid_{A=a}$ denotes the conditional distribution of $B$ given that $A = a$ for jointly distributed random variables $A$ and $B$).

Then $\| X - Y \| < \epsilon + \delta$.

The next fact says that if two distributions have small statistical difference, then their mass functions must be close at most points.

Fact 2.6 If $X$ and $Y$ are any two distributions such that $\| X - Y \| < \epsilon$, then with probability $> 1 - 2\sqrt{\epsilon}$ over $x \leftarrow X$,

$$(1 - \sqrt{\epsilon}) \Pr[X = x] < \Pr[Y = x] < (1 + \sqrt{\epsilon}) \Pr[X = x]$$

2.4 Zero-knowledge proofs

Before defining zero knowledge, we need to introduce some more terminology. Recall that a PPT algorithm is a probabilistic algorithm which runs in strict polynomial time. A function $f(n)$ is negligible if for all polynomials $p(n)$, $f(n) \leq \frac{1}{p(n)}$ for all sufficiently large $n$.

We follow Goldwasser, Micali, and Rackoff [GMR89] and Goldreich [Gol01] in defining interactive proofs and zero-knowledge. The original definitions in [GMR89] were given for languages. We generalize these definitions to promise problems in the natural way, as previously done in [GK93]. That is, conditions previously required for inputs in the language are now required for YES instances.
of a promise problem and conditions previously required for inputs not in the language are now required for no instances.

Informally, an interactive proof is a protocol in which a computationally unbounded prover attempts to convince a polynomial-time verifier \( V \) that an assertion is true, \textit{i.e.} that a string \( x \) is a YES instance of a promise problem. More formally, an interactive protocol \((P, V)\) between a computationally unbounded prover \( P \) and a PPT verifier \( V \) is said to be an interactive proof system for a promise problem \( \Pi \) with completeness error \( c(n) \) and soundness error \( s(n) \) if

1. If \( x \in \Pi_Y \), then \( \Pr[(P, V)(x) = \text{accept}] \geq 1 - c(|x|) \).

2. If \( x \in \Pi_N \), then for all \( P^* \), \( \Pr[(P^*, V)(x) = \text{accept}] \leq s(|x|) \).

We always require that \( 1 - c(n) > s(n) + 1/\text{poly}(n) \) and that both can be computed in time \( \text{poly}(n) \); under this assumption, parallel repetition can be used to obtain a new interactive proof for \( \Pi \) with completeness error and soundness error \( 2^{-n^k} \), for any constant \( k \). We say that \((P, V)\) exchanges \( m(n) \) messages if the prover and verifier exchange at most \( m(n) \) messages on any input of length \( n \). An interactive proof system is said to be public coin if on every input, the verifier’s random coins \( r \) can be written as a concatenation of strings \( r_1 r_2 \cdots r_t \) such that the \( i \)th message sent from the verifier to the prover is simply \( r_i \).

Roughly speaking, an interactive proof is said to be zero knowledge if, when the input is a YES instance, the verifier can simulate its view of the interaction on its own. To formalize this, let \((P, V)\) be an interactive proof system for a promise problem \( \Pi \). Let \( \text{View}_{P,V}(x) \) be a random variable describing the random coins of \( V \) and the messages exchanged between \( P \) and \( V \) during their interaction on input \( x \). \((P, V)\) is said to be a statistical zero-knowledge proof system against the honest verifier if there exists a PPT simulator \( S \) and a negligible function \( \alpha \) (called the simulator deviation) such that

\[
\text{If } x \in \Pi_Y, \text{ then } \| S(x) - \text{View}_{P,V}(x) \| \leq \alpha(|x|). \tag{2}
\]

A perfect zero-knowledge proof system is defined in the same way, except that (2) is replaced by \( \| S(x) - \text{View}_{P,V}(x) \| = 0 \), where \( S \) is allowed to output ‘fail’ with probability at most 1/2 and \( S(x) \) denotes the conditional distribution of \( S \) given that the output is not fail.\(^3\) A computational zero-knowledge proof system replaces (2) with the requirement that \( \{ S(x) \}_{x \in \Pi_Y} \) and \( \{ \text{View}_{P,V}(x) \}_{x \in \Pi_Y} \) are computationally indistinguishable [GM84, Yao82] ensembles of distributions. That is, for every nonuniform polynomial-time algorithm \( D \), there is a negligible function \( \alpha \) such that \( | \Pr[D(x, S(x)) = 1] - \Pr[D(x, \text{View}_{P,V}(x)))] | \leq \alpha(|x|) \) for all \( x \in \Pi_Y \).

We let \( \text{SZK} \) (resp. \( \text{PZK}, \text{CZK} \)) denote the class of promise problems with statistical (resp. perfect, computational) zero-knowledge proof systems against the honest verifier.

\textbf{Remarks on the definitions.}

1. (Honest verifiers) We only require that the zero-knowledge condition hold against the honest verifier, \textit{i.e.} the verifier that follows the protocol as specified. The usual definition requires the zero-knowledge property to hold against any polynomial-time verifier strategy. However, subsequent to this work, it has been shown that any proof system which is statistical zero knowledge against the honest verifier can be transformed into one that is zero knowledge against cheating verifiers [GSV98]. Via this transformation, many of our results directly translate to the class of promise problems possessing statistical zero-knowledge proofs against cheating verifiers. This is discussed in detail in Section 5.4.

\(^3\)A failure probability can also be allowed in the definition of statistical zero-knowledge, but this can easily be reduced to an \( 2^{-n^k} \) for any constant \( k \) by repeated trials and absorbed into the simulator deviation.
2. (Error probabilities) The completeness and soundness error probabilities can be made exponentially small without increasing the number of rounds, because zero-knowledge against an honest verifier is preserved under parallel repetition.

3. (Strict polynomial-time simulation) Following Goldreich [Gol01], we work with the variant of zero knowledge in which the simulator is required to run in strict polynomial time, with some probability of failure in the perfect case. The original definition in [GMR89] allows the simulator to run in expected polynomial time, but with zero probability of failure. Our choice is not very restrictive, because we are only discussing honest-verifier statistical zero-knowledge and we do not know of any problems which require an expected polynomial time simulator for the honest verifier. In addition, as shown in Section 5.1, our techniques can be used to prove that expected polynomial-time simulators and strict polynomial-time simulators are actually equivalent for public-coin statistical zero-knowledge proofs against an honest verifier.

4. (Promise problems vs. languages) Our definitions above generalize the original definitions of [GMR89] from languages to promise problems, and we focus on the “promise class” $\text{SZK}$ rather than the class of languages possessing statistical zero-knowledge proofs. As this was discussed in Section 2.1, here we simply reiterate the main justifications for this extension. First, for essentially all of our results, the fact that we prove them for the promise class only makes them stronger, by virtue of the fact that the promise class contains the language class. Second, several of the most important natural problems known to be in $\text{SZK}$, such as those in [GK93, GG98], are not languages, but promise problems, so it may actually be preferable to study the promise class.

Our only result which requires new interpretation for the language class is the Completeness Theorem (Thm. 3.1 below). As the complete problem is a promise problem, it is not complete for the language class in the usual sense. Nevertheless, it still gives a characterization of the language class, in that a language has a statistical zero-knowledge proof if and only if it reduces to the complete problem. (This requires that $\text{SZK}$ is closed under reductions (Corollary 4.3), which we will prove using the Completeness Theorem.)

We refer the reader to Goldreich [Gol01] for a more detailed discussion of the definitional issues with zero-knowledge proofs and a wider perspective on the subject.

3 The Completeness Theorem

3.1 The complete problem

The main aim of this paper is to demonstrate that $\text{SZK}$ consists exactly of the problems that involve deciding whether two efficiently samplable distributions are either far apart or close together. This can be formally captured by the following promise problem $\text{Statistical Difference}$ (abbreviated SD):

$$\text{SD}_Y = \left\{(C_0, C_1) : \|C_0 - C_1\| > \frac{2}{3}\right\}$$

$$\text{SD}_N = \left\{(C_0, C_1) : \|C_0 - C_1\| < \frac{1}{3}\right\}$$

In the above definition, $C_0$ and $C_1$ are circuits; these define probability distributions as discussed in Section 2. The thresholds of $1/3$ and $2/3$ in this definition are not completely arbitrary; it is important for the Polarization Lemma of Section 3.2 that $(2/3)^2 > 1/3$. 

10
We can now state the main theorem of the paper.

**Theorem 3.1 (Completeness Theorem)**  **Statistical Difference** is complete for SZK.

The most striking thing about Theorem 3.1 is that it characterizes statistical zero knowledge *with no reference to interaction or zero knowledge*. Future investigation of the class SZK can focus on the single problem SD, instead of dealing with arbitrarily complicated protocols, problems, and simulators.\(^4\)

We emphasize that the novelty of this result lies in the specific complete problem we present and not merely the existence of a complete promise problem. For example, it is fairly straightforward to construct a complete promise problem for PZK involving descriptions of Turing machines for the verifier and simulator. (See Appendix B.) However, in contrast to SD, a complete problem constructed in this manner is essentially restatement of the definition of the class and therefore does not simplify the study of the class at all.

The proof of Theorem 3.1 will come in Sections 3.3 and 3.4 via two lemmas and a theorem of Okamoto [Oka00]. But first, we observe that a statement analogous to Theorem 3.1 can be made for BPP, if we generalize BPP to promise problems in the obvious way.

**Proposition 3.2** If SD\(^{\prime}\) is the promise problem obtained by modifying the definition of SD so that \(C_0\) and \(C_1\) only have 1 bit of output, then SD\(^{\prime}\) is complete for BPP.

**Proof:** To see that SD\(^{\prime}\) is in BPP, first observe that for circuits \(C_0\) and \(C_1\) (or any random variables) that always output either 0 or 1,

\[
\|C_0 - C_1\| = |\Pr[C_0 = 1] - \Pr[C_1 = 1]|.
\]

Thus, an estimate on \(\|C_0 - C_1\|\) that is correct within an additive factor of 1/3 can be obtained by sampling \(C_0\) and \(C_1\) polynomially many times and counting the number of ones that occur for each. This is sufficient to decide SD\(^{\prime}\).

Now we show that every promise problem \(\Pi\) in BPP reduces to SD\(^{\prime}\). Let \(A\) be the PPT machine which outputs 1 with probability greater than 2/3 when \(x \in \Pi_V\), but outputs 1 with probability less than 1/3 when \(x \in \Pi_N\). Let \(p(n)\) be a polynomial bound on the running time of \(A\). Given an input \(x\), we can, by standard techniques,\(^5\) produce in polynomial time a circuit \(C_x\) describing the computation of \(A\) on \(x\) for \(p(|x|)\) steps. The input to \(C_x\) is the first \(p(|x|)\) bits on the random tape of \(A\) and the output is the first bit on the output tape. Let \(D\) be a circuit that always outputs 0. Then \(\|C_x - D\| = \Pr[A(x) = 1]\), so \(x \mapsto (C_x, D)\) is a polynomial-time reduction from \(\Pi\) to SD\(^{\prime}\).

Proposition 3.2 remains true even if we allow \(C_0\) and \(C_1\) to output strings of logarithmic length. Other classes such as P and co-RP can be obtained by modifying the definition of SD in a similar fashion (and changing the thresholds). This demonstrates that SZK is a natural generalization of these well-known classes.

---

\(^4\)It should be noted that completeness is most meaningful for classes that are closed under reductions, which is not a priori clear for SZK. Later, we will prove that SZK is indeed closed under reductions, as a corollary of the Completeness Theorem itself (Corollary 4.3).

\(^5\)See, for example, [Pap94, Thms. 8.1 and 8.2].
3.2 A polarization lemma

In this section, we exhibit a transformation which “polarizes” the statistical relationship between two distributions. That is, pairs of distributions which are statistically close become much closer and pairs of distributions which are statistically far apart become much further apart.

**Lemma 3.3 (Polarization Lemma)**\(^6\) There is a polynomial-time computable function that takes a triple \( (C_0, C_1, 1^k) \), where \( C_0 \) and \( C_1 \) are circuits, and outputs a pair of circuits \( (D_0, D_1) \) such that

\[
\begin{align*}
\| C_0 - C_1 \| < 1/3 & \implies \| D_0 - D_1 \| < 2^{-k} \\
\| C_0 - C_1 \| > 2/3 & \implies \| D_0 - D_1 \| > 1 - 2^{-k}
\end{align*}
\]

The usefulness of the Polarization Lemma comes from the fact that the two distributions it produces can be treated almost as if they were identically distributed or disjoint (i.e. statistical difference 0 and 1, respectively). Indeed, it will be essential in proving that SD (with thresholds of 2/3 and 1/3, as we’ve defined it) is in SZK and we will make further use of it in deriving consequences of Theorem 3.1.

Superficially, it may seem that a Chernoff bound argument is all that is needed to prove Lemma 3.3. However, Chernoff bounds are primarily useful for distinguishing between two events. This corresponds to increasing statistical difference, as formalized in the following “direct product” lemma:

**Lemma 3.4 (Direct Product Lemma)** Let \( X \) and \( Y \) be distributions such that \( \| X - Y \| = \epsilon \). Then for all \( k \),

\[ k\epsilon \geq \| \otimes^k X - \otimes^k Y \| \geq 1 - 2 e^{-k\epsilon^2/2} \]

**Proof:** The upper bound of \( k\epsilon \) follows immediately from Fact 2.3, so we proceed to the proof of the lower bound. Recall, from the definition of statistical difference, that there must exist a set \( S \) such that

\[ \Pr[X \in S] - \Pr[Y \in S] = \epsilon. \]

Let \( p = \Pr[Y \in S] \), so \( \Pr[X \in S] = p + \epsilon \). Hence, in \( k \) independent samples of \( X \), the expected number of samples that lie in \( S \) is \( (p + \epsilon)k \), whereas in \( k \) independent samples of \( Y \), the expected number of samples that lie in \( S \) is \( pk \). The Chernoff bound\(^7\) tells us that the probability that \( \text{at least} \ (p + \frac{\epsilon}{2})k \) components of \( \otimes^k Y \) lie in \( S \) is at most \( \exp(-k\epsilon^2/2) \), whereas the probability that \( \text{at most} \ (p + \frac{\epsilon}{2})k \) components of \( \otimes^k X \) lie in \( S \) is at most \( \exp(-k\epsilon^2/2) \). Let \( S' \) be the set of all \( k \)-tuples that contain more than \( (p + \frac{\epsilon}{2})k \) components that lie in \( S \). Then,

\[ \| \otimes^k X - \otimes^k Y \| \geq \Pr[\otimes^k X \in S'] - \Pr[\otimes^k Y \in S'] \geq 1 - 2 e^{-k\epsilon^2/2}. \]

\[ \blacksquare \]

Note the gap between the upper and lower bounds in Lemma 3.4; the lower bound says that taking \( O(1/\epsilon^2) \) copies is sufficient to increase statistical difference from \( \epsilon \) to a constant, while the upper bound says that \( \Omega(1/\epsilon) \) copies are necessary. This gap is inherent, as the following

\(^6\)The Polarization Lemma stated here is called the Amplification Lemma in [SV97]. We change the name here to stress that the Polarization Lemma does not merely increase statistical difference.

\(^7\)For the formulation of the Chernoff bound we use, see, for example, the formulation of Hoeffding’s inequality in [Hof95, Sec. 7.2.1].
example illustrates: Taking $X$ and $Y$ to be distributions on \{0, 1\} that are 1 with probability 1 and $1 - \epsilon$, respectively, we see that the statistical difference between $\otimes^k X$ and $\otimes^k Y$ is exactly $1 - (1 - \epsilon)^k$, which is a constant for $k = \Theta(1/\epsilon)$. On the other hand, when $X$ and $Y$ are 1 with probability $(1 + \epsilon)/2$ and $(1 - \epsilon)/2$, respectively, it can be shown that $k = \Theta(1/\epsilon^2)$ copies are necessary to increase the statistical difference to a constant. Furthermore, in this latter example, $\|X \otimes X - Y \otimes Y\| = \epsilon = \|X - Y\|$, so we cannot even hope to show that statistical difference always increases for every $k > 1$ (as pointed out to us by Madhu Sudan).

Notice that the Direct Product Lemma 3.4 is not sufficient to prove the Polarization Lemma, because it only increases statistical difference, whereas we would like to increase statistical difference in some cases and decrease it in others. However, it does drive larger values of the statistical difference to 1 more quickly than it drives smaller values to 0, so it is a step in the right direction. The following lemma provides a complementary technique which decreases the statistical difference to 0, with small values going to 0 faster than large values.

**Lemma 3.5 (XOR Lemma)** There is a polynomial-time computable function that maps a triple $(C_0, C_1, 1^k)$, where $C_0$ and $C_1$ are circuits, to a pair of circuits $(D_0, D_1)$ such that $\|D_0 - D_1\| = \|C_0 - C_1\|^{1/k}$. Specifically, $D_0$ and $D_1$ are defined as follows:

$D_0$: Uniformly select $(b_1, \ldots, b_k) \in \{0, 1\}^k$ such that $b_1 \oplus \cdots \oplus b_k = 0$, and output a sample of $C_{b_1} \otimes \cdots \otimes C_{b_k}$.

$D_1$: Uniformly select $(b_1, \ldots, b_k) \in \{0, 1\}^k$ such that $b_1 \oplus \cdots \oplus b_k = 1$, and output a sample of $C_{b_1} \otimes \cdots \otimes C_{b_k}$.

In order to prove this lemma, we employ a generalization of the technique used in [DDPY94] to represent the logical AND of statements about **GRAPH NONISOMORPHISM**. This tool is described in the following Proposition.

**Proposition 3.6** Let $X_0, X_1, Y_0, Y_1$ be any random variables, and define the following pair of random variables:

$Z_0$: Choose $a, b \in R\{0, 1\}$ such that $a \oplus b = 0$. Output a sample of $X_a \otimes Y_b$.

$Z_1$: Choose $a, b \in R\{0, 1\}$ such that $a \oplus b = 1$. Output a sample of $X_a \otimes Y_b$.

Then $\|Z_0 - Z_1\| = \|X_0 - X_1\| \cdot \|Y_0 - Y_1\|$.

The statistical difference between $X_0$ and $X_1$ (or $Y_0$ and $Y_1$) measures the advantage a computationally unbounded party has, over random guessing, in guessing $b$ given a sample from $X_b$, where $b$ is selected uniformly from $\{0, 1\}$. (This view of statistical difference will become more apparent in the subsequent section.) Intuitively, the above Proposition says that the advantage one has in guessing the XOR of two independent bits is the product of the advantages one has for guessing each individual bit.

**Proof:**

$$\|Z_0 - Z_1\| = \frac{1}{2} \|Z_0 - Z_1\|_1 = \frac{1}{2} \left\| \left( \frac{1}{2} X_0 \otimes Y_0 + \frac{1}{2} X_1 \otimes Y_1 \right) - \left( \frac{1}{2} X_0 \otimes Y_0 + \frac{1}{2} X_0 \otimes Y_1 \right) \right\|_1 = \frac{1}{4} \|X_0 - X_1\| \otimes (Y_0 - Y_1)_1$$
\[
= \left( \frac{1}{2} |X_0 - X_1| \right) \cdot \left( \frac{1}{2} |Y_0 - Y_1| \right)
= \|X_0 - X_1\| \cdot \|Y_0 - Y_1\|
\]

Recall that the penultimate equality above follows because \( |v \otimes w| = |v| \cdot |w| \).

Proposition 3.6 and an induction argument establish Lemma 3.5. Yao’s XOR Lemma [Yao82] (cf., [GNW95]) can be seen as an analogue of Lemma 3.5 in the computational setting, where the analysis is much more difficult.\(^8\)

Now we combine the Direct Product and XOR constructions of Lemmas 3.4 and 3.5 to prove Lemma 3.3. The Direct Product Lemma gives a way to increase statistical difference with large values going to 1 faster than small values. Similarly, the XOR Lemma shows how to decrease statistical difference with small values going to 0 faster than large values. Intuitively, alternating these procedures should “polarize” large and small values of statistical difference, pushing them closer to 1 and 0, respectively. A similar alternation between procedures with complementary effects was used by Ajtai and Ben-Or [AB84] to amplify the success probability of randomized constant-depth circuits.

**Proof:** Let \( \ell = \lceil \log_{4/3} 6k \rceil \). Apply Lemma 3.5 to the triple \((C_0, C_1, 1^\ell)\) to produce \((C_0', C_1')\) such that if
\[
\|C_0 - C_1\| < 1/3 \implies \|C_0' - C_1'\| < (1/3)^\ell
\]
\[
\|C_0 - C_1\| > 2/3 \implies \|C_0' - C_1'\| > (2/3)^\ell.
\]
Let \( m = 3^{\ell-1} \). Let \( C_0'' = \otimes^m C_0'\) and let \( C_1'' = \otimes^m C_1'\). Then, by Fact 2.3 and the Direct Product Lemma,
\[
\| C_0 - C_1\| < 1/3 \implies \| C_0'' - C_1''\| < 1/3
\]
\[
\| C_0 - C_1\| > 2/3 \implies \| C_0'' - C_1''\| > 1 - 2 \exp(3^{\ell-1} (2/3)^{2\ell}/2) > 1 - 2e^{-k}.
\]

Finally, apply the transformation of Lemma 3.5 one more time to \((C_0'', C_1'', 1^k)\) to produce \((D_0, D_1)\) such that
\[
\| C_0 - C_1\| < 1/3 \implies \| D_0 - D_1\| < 3^{-k} < 2^{-k}
\]
\[
\| C_0 - C_1\| > 2/3 \implies \| D_0 - D_1\| > (1 - 2e^{-k})^k > 1 - 2k e^{-k} > 1 - 2^{-k}.
\]

Notice that the above analysis relies on the fact that \((2/3)^2 > (1/3)\), so it will not work if 2/3 and 1/3 are replaced by, say, .51 and .49. We do not know how to prove such a Polarization Lemma for arbitrary constant thresholds. We can however extend it to thresholds \( \alpha \) and \( \beta \), where \( \alpha^2 > \beta \), and the running time will be polynomial in \( 1/(\alpha - \beta) \) and \( \exp(1/\delta) \), where \( \delta \) is defined by \( \alpha^{2+\delta} = \beta \), along with the input size. See [SV99] for more details.

---

\(^8\)To see the analogy: recall that Yao’s XOR Lemma considers the maximum advantage an efficient algorithm has, over random guessing, in computing a bit \( b \) from string \( x \) when they are selected according to some distribution \((b, x) \leftarrow (B, X)\) (e.g., \( X \) is uniform and \( B \) is a hardcore bit of \( f^{-1}(X) \) for some one-way permutation \( f \)). It states that the maximum advantage an efficient algorithm has in computing the XOR \( b_1 \oplus \cdots \oplus b_k \) from \((x_1, \ldots, x_k)\) decreases exponentially with \( k \) when the pairs \((b_i, x_i)\) are independently distributed according to \((B, X)\).
3.3 A protocol for Statistical Difference

In this section, we show that SD has a simple two-message statistical zero-knowledge proof system, which is a generalization of the standard protocols for QUADRATIC NONRESIDUOty [GMR89] and GRAPH NONISOMORPHISM [GMW91]. Intuitively, if two distributions are statistically far apart, then, when given a random sample from one of the distributions, a computationally unbounded party should have a good chance of guessing from which distribution it came. However, if the two distributions are statistically very close, even a computationally unbounded party should not have much better than a 50% chance of guessing correctly. This suggests the following two-message protocol for SD (note that this protocol is not a public-coin protocol):

Zero-knowledge Proof System for SD

Input: \((C_0, C_1)\) (such that either \(\|C_0 - C_1\| > 2/3\) or \(\|C_1 - C_1\| < 1/3\))

1. \(V, P\): Compute \((D_0, D_1) = \text{Polarize}(C_0, C_1, 1^n)\), where \(n = \|(C_0, C_1)\|\).
2. \(V\): Flip one random coin \(r \leftarrow \{0, 1\}\). Let \(z\) be a sample of \(D_r\). Send \(z\) to \(P\).
3. \(P\): If \(\Pr[D_0 = z] > \Pr[D_1 = z]\), answer 0, otherwise answer 1.
4. \(V\): Accept if \(P\)'s answer equals \(r\), reject otherwise.

**Lemma 3.7** The above is a statistical zero-knowledge proof system for SD, with soundness error \(1/2 + 2^{-n}\), and completeness error and simulator deviation both \(2^{-n}\). Thus SD \(\in \text{SZK}\).

**Proof:** We will observe that the prover strategy given in the protocol is optimal (i.e. maximizes the verifier's acceptance probability), and use this to bound both the soundness and completeness error. The simulator deviation will then follow easily.

Indeed the optimality of the given prover strategy follows from a standard argument: Consider any prover \(P^*\). Suppose for some \(z\) the prover \(P^*\) fails to follow the strategy we present. If \(\Pr[D_0 = z] \neq \Pr[D_1 = z]\), this means that with nonzero probability, \(P^*\) chooses the distribution in which \(z\) is less likely to occur. Then, conditioned on \(z\), the success probability of \(P^*\) will certainly be lower than that of the prover in our protocol. If \(\Pr[D_0 = z] = \Pr[D_1 = z]\), the prover has no information about \(r\), so no matter what strategy it uses, it has exactly even odds of guessing correctly. Since these observations hold for all \(z\), the given prover is optimal.

We now analyze the probability of success of the optimal prover. Recall that \(\|D_0 - D_1\| = \Pr[D_0 \in S] - \Pr[D_1 \in S]\) for \(S = \{z : \Pr[D_0 = z] > \Pr[D_1 = z]\}\). The probability that the optimal prover guesses correctly is exactly

\[
\frac{1}{2} \Pr[D_0 \in S] + \frac{1}{2} \Pr[D_1 \notin S] = \frac{1}{2} \left(\Pr[D_0 \in S] + 1 - \Pr[D_1 \in S]\right) = \frac{1 + \|D_0 - D_1\|}{2}.
\]

By Lemma 3.3, \(\|D_0 - D_1\| > 1 - 2^{-n}\) when \((C_0, C_1)\) is a YES instance of SD, and \(\|D_0 - D_1\| < 2^{-n}\) when \((C_0, C_1)\) is a NO instance. Hence, the probability that the prover convinces the verifier to accept is greater than \((1 + 1 - 2^{-n})/2 > 1 - 2^{-n}\) for YES instances, and less than \((1 + 2^{-n})/2 < 1/2 + 2^{-n}\) for NO instances. This immediately gives the completeness error; the soundness error also follows because we considered the optimal prover strategy.
Now, notice that when the prover answers correctly, all the verifier receives from the prover is the value of \( r \), which the verifier already knew. Thus, since we have shown that the prover is answering correctly with all but exponentially small probability, intuitively the verifier learns nothing. To turn this intuition into a proof of statistical zero knowledge, we consider the following probabilistic polynomial-time simulator: On input \((C_0, C_1)\), the simulator first computes \((D_0, D_1) = \text{Polarize}(C_0, C_1, 1^n)\), where \( n = |(C_0, C_1)| \). The simulator then flips one random coin \( r \in \{0, 1\} \). If \( r = 0 \), it samples \( z \) from \( D_0 \), otherwise it samples \( z \) from \( D_1 \). The simulator then outputs a conversation in which the verifier sends \( z \) to the prover, and the prover responds with \( r \). The simulator also outputs the random coins it used to generate \( r \) and \( z \) as the coins of the verifier. Thus, the simulator presented here always outputs conversations in which the prover responds correctly. Except for the prover’s response, all other components of the simulator’s output distribution are distributed identically to the verifier’s view of the real interaction. Hence, the simulator deviation is bounded by the probability that the prover responds incorrectly in the real interaction, which we have already argued is at most \( 2^{-n} \) in the case of \textsc{Yes} instances. 

Note that the above proof system remains complete and sound even without polarization, but for the zero-knowledge property, we need to make the statistical difference very close to 1 on \textsc{Yes} instances.

By using a security parameter \( k \) rather than \( n \) in the call to \text{Polarize}, both the completeness error and simulator deviation can be reduced to \( 2^{-k} \). Thus, even very short assertions about SD can be proven with very high security. Contrast this with the original definition of \text{SZK} [GMR89], which only requires that the simulator deviation vanish as an negligible function of the input length. This property has obvious cryptographic significance, so we formulate it more precisely in Section 4.1.

### 3.4 \text{SZK}-hardness of \text{SD}

The other main lemma we prove to show that \text{SD} is complete for \text{SZK} follows:

**Lemma 3.8** Suppose promise problem \( \Pi \) has a public coin statistical zero-knowledge proof system. Then there exist PPTs \( A \) and \( B \) and a negligible function \( \alpha \) such that

\[
x \in \Pi_Y \implies \| A(x) - B(x) \| \leq \alpha(|x|), \text{ and}
\]

\[
x \in \Pi_N \implies \| A(x) - B(x) \| \geq 1 - 2^{-\alpha(|x|)}.
\]

We defer the proof of this lemma to Section 3.5, and first observe how it gives a reduction to \text{SD} for problems with public-coin statistical zero-knowledge proofs.

**Corollary 3.9** Suppose promise problem \( \Pi \) has a public-coin statistical zero-knowledge proof system. Then \( \Pi \) reduces to \text{SD}. (Equivalently, \( \Pi \) is reduces to \text{SD}.)

**Proof:** First apply Lemma 3.8 to obtain \( A \) and \( B \), with \( p(|x|) \) being a polynomial bound on the running times of \( A(x) \) and \( B(x) \). Given a string \( x \), we can, by standard techniques,\(^9\) produce in polynomial time circuits \( C_0 \) and \( C_1 \) simulating the computation of \( A \) and \( B \), respectively, on \( x \) for \( p(|x|) \) steps. The inputs to \( C_0 \) and \( C_1 \) are the first \( p(|x|) \) bits on the random tapes of \( A \) and \( B \) and the outputs are the first \( p(|x|) \) positions on the output tapes. Then \( \| C_0 - C_1 \| = \| A(x) - B(x) \| \), which is at most \( \alpha(|x|) < 1/3 \) if \( x \in \Pi_Y \) and at least \( 1 - 2^{-k|} > 2/3 \) if \( x \in \Pi_N \) (for all sufficiently

\(^9\)See, for example, [Pap94, Thms. 8.1 and 8.2].
long $x$). So $x \mapsto (C_0, C_1)$ is a reduction from $\Pi$ to $\overline{SD}$ (for all but finitely many $x$). ■

The final ingredient in the proof of Theorem 3.1 is a theorem of Okamoto [Oka00], which we state in terms of promise problems.  

**Theorem 3.10 ([Oka00, Thm. 1])** If a promise problem $\Pi$ has a statistical zero-knowledge proof system, then $\Pi$ has a public-coin statistical zero-knowledge proof system.

Now it will be easy to show that $SD$ is complete for $SZK$.

**Proof of Theorem 3.1:** Lemma 3.7 tells us that $SD \in SZK$, so we only need to show that every problem in $SZK$ reduces to $SD$. Corollary 3.9 and Theorem 3.10 imply that every problem $\Pi \in SZK$ reduces to $\overline{SD}$. In particular, $SD$ reduces to $\overline{SD}$, or, equivalently, $\overline{SD}$ reduces to $SD$. Composing reductions, it follows that every problem $\Pi \in SZK$ reduces to $SD$. ■

### 3.5 Proof of Lemma 3.8

**Intuition.** Recall that we wish to construct a pair of probabilistic polynomial-time machines $A$ and $B$ such that if $x \in \Pi_Y$, the distributions $A(x)$ and $B(x)$ are statistically very close, but when $x \in \Pi_N$, $A(x)$ and $B(x)$ are far apart. We are given that $\Pi$ has a public-coin statistical zero-knowledge proof system. A natural place to search for the desired distributions is in the output of the simulator for this proof system. We wish to find properties of the simulator’s output that (1) distinguish the case $x \in \Pi_Y$ from $x \in \Pi_N$, and (2) are captured by the statistical difference between samplable distributions. Following [AH91], we think of the simulator as describing the moves of a virtual prover and a virtual verifier.

In the case that $x \in \Pi_Y$, we have strong guarantees on the simulator’s output. Namely, its output distribution is statistically very close to the real interaction. In particular, it outputs accepting conversations with high probability and the virtual prover and verifier “behave” similarly to the real prover and verifier.

When $x \in \Pi_N$, there are two cases. If the simulator outputs accepting conversations with low probability, this easily distinguishes it from the simulator output when $x \in \Pi_Y$. However, it is possible that the simulator will output accepting conversations with high probability even when $x \in \Pi_N$. This means that the virtual prover is doing quite well in fooling the virtual verifier. This naturally suggests a strategy for a real prover — imitate the virtual prover’s behavior. Such a prover, called a simulation-based prover, was introduced by Fortnow [For89] and is a crucial construct in our proof.

The soundness of the proof system tells us that the simulation-based prover cannot hope to convince the real verifier with high probability. There must be a reason for this discrepancy between the success rates of the virtual prover and the simulation-based prover. Since the virtual prover behaves exactly like the simulation-based prover, it must be that the virtual verifier does not behave like the real verifier. Note that in a public-coin proof system, the behavior of the real verifier is extremely simple: it chooses each of its messages independently and uniformly at random. If the virtual verifier does not behave as the real verifier, then it must be that either the virtual verifier’s messages are far from uniform, or that they are dependent on previous messages.

---

10 Okamoto stated his result in terms of languages, but the proof readily extends to promise problems (cf., [GV99]).
We therefore exhibit two efficiently samplable distributions, one describing the messages of the real verifier, and the other describing the messages of the virtual verifier. We show that if \( x \in \Pi_Y \), these two distributions must be nearly identical; whereas if \( x \in \Pi_N \), they must be far apart.

The basic approach described above is quite similar to the approaches developed in previous work on SZK, such as that of Fortnow [For89], Aiello and Håstad [AH91], and Ostrovsky [Ost91]. However, by focusing on public-coin proofs (thanks to Theorem 3.10 [Oka00]), we are able to carry out a cleaner analysis and reach a novel conclusion (namely, the Completeness Theorem).

**Notation.** Let \((P, V)\) be a public-coin interactive proof system for a promise problem \(\Pi\) which is (honest-verifier) statistical zero knowledge and let \(S\) be a simulator for this proof system. Without loss of generality, we may assume that the interaction of \(P\) and \(V\) on input \(x\) always has \(2r(|x|)\) exchanged messages, with \(V\) sending the first message and each message consisting of exactly \(q(|x|)\) bits, for some polynomials \(q\) and \(r\). Moreover, it may be assumed that \(S\)'s output always consists of \(2r(|x|)\) strings of length \(q(|x|)\). The output of \(S\) and the conversation between \(P\) and \(V\) on input \(x\) will be written in the form \(S(x) = (c_1, p_1, \ldots, c_r, p_r)_S\) and \((P, V)(x) = (c_1, p_1, \ldots, c_r, p_r)_{(P, V)}\), respectively, where \(c_1, \ldots, c_r\) represent the messages (equivalently coin tosses, since we are in the public-coin setting) of \(V\), \(p_1, \ldots, p_r\) represent the prover messages, and \(r = r(|x|)\). (Dependence on \(x\) will often be omitted in this manner for notational convenience.) We use notation such as \((c_i)_S\) for the random variable obtained by running \(S\) once and taking the \(c_i\)-component of its output. More generally, partial conversation transcripts will be written like \((c_1, p_1, c_2, p_2)_S\). We call a conversation transcript \((c_1, p_1, \ldots, c_r, p_r)\) which would make \(V\) accept (resp., reject) an **accepting conversation** (resp., **rejecting conversation**). We denote by \(U(n)\) the uniform distribution on strings of length \(n\).

**The proof.** In order to formalize the above intuition, a definition of the simulation-based prover needs to be given. This is the prover \(P^*\) that imitates the virtual prover, i.e. \(P^*\) does the following to compute its next message when the current conversation transcript is \((c_1, p_1, \ldots, c_i)\):

- If \(S(x)\) outputs conversations that begin with \((c_1, p_1, \ldots, c_i)\) with probability 0, then output \(q(x)\).
- Else output \(y \in \{0, 1\}^q(|x|)\) with probability

  \[
  p_y = \Pr[S(x) \text{ begins with } (c_1, p_1, \ldots, c_i, y) | S(x) \text{ begins with } (c_1, p_1, \ldots, c_i)].
  \]

In order to analyze the success probability of \(P^*\), we first compare the output of \(S\) to the actual conversations between \(P^*\) and \(V\). For \(i = 1, \ldots, r\), consider the distributions \(A_i = (c_1, p_1, \ldots, c_{i-1}, p_{i-1}, c_i)_S\) and \(B_i = (c_1, p_1, \ldots, c_{i-1}, p_{i-1})_S \otimes U(q(|x|))\), and let \(\epsilon_i = \|A_i - B_i\|\). The last component of \(A_i\) is a move of the virtual verifier whereas the last component of \(B_i\) is chosen uniformly and independently of the history, just like a move of the real verifier. Thus, the \(\epsilon_i\)'s measure the similarity between the behavior of the virtual verifier and the real verifier.

The following claim formalizes our intuition that, if the virtual verifier and real verifier have similar behavior, then the interaction between the simulation-based prover \(P^*\) and the real verifier \(V\) is similar to the interaction between the virtual prover and virtual verifier (as described by the simulator).

**Claim 3.11** \(\|S(x) - (P^*, V)(x)\| \leq \sum_{i=1}^{r} \epsilon_i\).

**Proof of claim:** Let \(C_i^S = (c_1^S, p_1, \ldots, c_i)_S\) be the random variable of partial simulator transcripts ending with the \(i\)-th coins of the virtual verifier. Let \(P_i^S = (c_1^S, p_1, \ldots, c_i, p_i)_S\)

18
be the random variable of partial transcripts ending with the $i$-th virtual prover response. Similarly define $C_i^*$ and $P_i^*$ as partial conversation transcripts of $(P^*, V)$. The aim is to show that at round $k$, the statistical difference grows by at most $\epsilon_k$. Formally, it will be shown by induction on $k$ that

$$\left\| P_k^S - P_k^* \right\| \leq \sum_{i=1}^{k} \epsilon_i$$

The case $k = 0$ is trivial. For general $k$, first note that since $P^*$ gives a response chosen according to the same distribution as the virtual prover, adding these responses to the conversations cannot increase the statistical difference (by Fact 2.4). That is,

$$\left\| P_{k+1}^S - P_{k+1}^* \right\| = \left\| C_{k+1}^S - C_{k+1}^* \right\|.$$

The idea now is to extract the parts of $\left\| C_{k+1}^S - C_{k+1}^* \right\|$ corresponding to $\epsilon_{k+1}$ and observe that what is left is simply the error from the previous round. Note that $C_{k+1}^* = P_k^* \oplus U(q(|x|))$, since the real verifier’s coins are always uniform and independent from what came before.

Then, applying Fact 2.3 and the Triangle Inequality,

$$\left\| C_{k+1}^S - C_{k+1}^* \right\| \leq \left\| C_{k+1}^S - P_k^S \oplus U(q(|x|)) \right\| + \left\| P_k^S \oplus U(q(|x|)) - P_k^* \oplus U(q(|x|)) \right\|$$

$$\leq \epsilon_{k+1} + \left\| P_k^S - P_k^* \right\| + \left\| U(q(|x|)) - U(q(|x|)) \right\|$$

$$\leq \epsilon_{k+1} + \sum_{i=1}^{k} \epsilon_i.$$

This completes the induction. Since $P_r^S = S(x)$ and $P_r^* = (P^*, V)(x)$, the Claim is proved.

We are now ready to construct the distributions we seek. The two distributions $A$ and $B$ each consist of $r + 1$ components, shown in Table 1. $A$ is the algorithm whose output on input $x$ is $(A_0(x), A_1(x), \ldots, A_r(x))$, all run independently, and $B$ is the algorithm whose output is $(B_0(x), B_1(x), \ldots, B_r(x))$, all run independently. Recall that, for $i \geq 1$, $\epsilon_i$ is the statistical difference between $A_i$ and $B_i$.

We will show that the statistical difference between $A$ and $B$ is negligible if $x \in \Pi_Y$ and is noticeable if $x \in \Pi_N$. Amplifying this gap by repetition will yield Lemma 3.8.

**Claim 3.12** There exists a negligible function $\alpha$ such that if $x \in \Pi_Y$, then $\|A(x) - B(x)\| \leq \alpha(|x|)$. 

<table>
<thead>
<tr>
<th>Algorithm $A$</th>
<th>Algorithm $B$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$A_0(x)$</td>
<td>Run $S(x)$ for $</td>
</tr>
<tr>
<td>$A_i(x)$</td>
<td>Run $S(x)$ to output $(c_1, p_1, \ldots, c_i)_{S(x)}$.</td>
</tr>
<tr>
<td>$B_0(x)$</td>
<td>Output 1.</td>
</tr>
<tr>
<td>$B_i(x)$</td>
<td>Run $S(x)$ and flip $q(</td>
</tr>
</tbody>
</table>
**Proof of claim:** The statistical difference between $A(x)$ and $B(x)$ is bounded above by the sum of the statistical differences between $A_i(x)$ and $B_i(x)$ over $i = 0, \ldots, r(|x|)$ (by Fact 2.3). First, let’s examine $i = 0$. Since $S(x)$ outputs a conversation which makes $V$ accept with probability at least $2/3 - \text{neg}(|x|)$, the Chernoff bound implies that $\Pr[A_0(x) = 1] = 1 - 2^{-\Omega(|x|)}$, so the statistical difference between $A_0$ and $B_0$ is negligible. For $i \geq 1$, recall that in the real conversations of $P$ and $V$, the verifiers’ coins are truly uniform and independent from prior rounds, so $\|A_i(x) - B_i(x)\|$ should essentially be bounded by the statistical difference between the simulator’s output and the real interaction. This is in fact true, as (omitting $x$ from the notation):

$$\|A_i - B_i\| \leq \|A_i - (c_1, p_1, \ldots, c_i)_{P, V}\| + \|(c_1, p_1, \ldots, c_i)_{P, V} - B_i\| \leq \|S - (P, V)\| + \|S - (P, V)\|.$$

Thus,

$$\|A(x) - B(x)\| \leq 2^{-\Omega(|x|)} + 2r(|x|) \cdot \|S(x) - (P, V)(x)\|,$$

which is negligible since $\|S(x) - (P, V)(x)\|$ is negligible and $r(x)$ is polynomial.

**Claim 3.13** If $x \in \Pi_N$ then $\|A(x) - B(x)\| \geq 1/12r(|x|)$.

**Proof of claim:** It suffices to show that for some $i$, $\epsilon_i = \|A_i(x) - B_i(x)\| > 1/12r(|x|)$ (by Fact 2.4). We deal with two cases depending on the probability that $S$ outputs an accepting conversation.

Case 1: $\Pr[S(x) \text{ accepts}] \leq 5/12$. Then, by the Chernoff bound, $\Pr[A_0(x) = 1] \leq 2^{-\Omega(|x|)}$, so the statistical difference between $A_0(x)$ and $B_0(x)$ is at least $1 - 2^{-\Omega(|x|)} > 1/12r(|x|)$.

Case 2: $\Pr[S(x) \text{ accepts}] > 5/12$. Then, since $\Pr[(P^*, V)(x) \text{ accepts}]$ is at most 1/3, we must have

$$\sum_{i=0}^{r} \epsilon_i \geq \|S(x) - (P^*, V)(x)\| = \frac{5}{12} - \frac{1}{3} = \frac{1}{12}.$$

Thus, at least one $\epsilon_i$ must be greater than $1/12r(|x|)$.

Now consider the samplable distributions $\tilde{A}(x) = \otimes s(|x|) A(x)$ and $\tilde{B}(x) = \otimes s(|x|) B(x)$, where $s(n) = n \cdot r(n)^2$. If $x \in \Pi_Y$, $\|\tilde{A}(x) - \tilde{B}(x)\| \leq s(|x|) \cdot \|A(x) - B(x)\|$, which is still negligible. If $x \in \Pi_N$, then by the Direct Product Lemma (Lemma 3.4), $\|\tilde{A}(x) - \tilde{B}(x)\| \geq 1 - 2^{-\Omega(|x|)}$. This completes the proof of Lemma 3.8. 

We illustrate the constructions in this lemma and the statistical zero-knowledge proof system for **Statistical Difference** for the specific example of **Graph Isomorphism** in Appendix C.

## 4 Applications

### 4.1 Efficient statistical zero-knowledge proofs

The proof system for **Statistical Difference** given in Section 3.3 has a number of desirable features. It is very efficient in terms of communication and interaction, and the simulator deviation
can be made exponentially small in a security parameter (that can be varied independently of the input length). By the Completeness Theorem, it follows that every problem in SZK also has a proof system with these properties.

We begin by formalizing one of these properties that was informally discussed in Section 3.3.

**Definition 4.1** An interactive protocol \((P, V)\) is called a security-parametrized statistical zero-knowledge proof system for a promise problem \(\Pi\) if there exists a PPT simulator \(S\), a negligible function \(\alpha(k)\) (called the simulator deviation), and completeness and soundness errors \(c(k)\) and \(s(k)\) such that for all strings \(x\) and all \(k \in \mathbb{N}\):

1. If \(x \in \Pi_Y\), then \(\Pr[(P, V)(x, 1^k) = \text{accept}] \geq 1 - c(k)\).
2. If \(x \in \Pi_N\), then for all \(P^*\), \(\Pr[(P^*, V)(x, 1^k) = \text{accept}] \leq s(k)\).
3. If \(x \in \Pi_Y\), then \(|S(x, 1^k) - \text{View}_{P,V}(x, 1^k)| \leq \alpha(k)\).

As usual, we require that \(c(k)\) and \(s(k)\) are computable in time \(\text{poly}(k)\) and \(1 - c(k) > s(k) + 1/\text{poly}(k)\)

We now describe the efficient proof systems inherited by all of SZK.

**Corollary 4.2** Every problem in SZK possesses a security-parameterized statistical zero-knowledge proof system with the following properties:

1. Simulator deviation \(2^{-k}\), completeness error \(2^{-k}\), and soundness error \(1/2 + 2^{-k}\).
2. The prover and verifier exchange only 2 messages.
3. The prover sends only 1 bit to the verifier.
4. The prover is deterministic.

**Proof:** Let \(\Pi\) be any promise problem in SZK. Let \(f\) be the reduction from \(\Pi\) to SD guaranteed by the Completeness Theorem. A protocol with the desired properties for \(\Pi\) can be obtained as follows: on input \((x, 1^k)\), execute the proof system for SD, given in Section 3.3, on input \(f(x)\) and using \(k\) rather than \(n\) in the call to Polarize. □

### 4.2 Closure properties

In this section, we prove several closure properties of SZK. The first, closure under reductions, is a direct consequence of the “security parametrization” property shown to hold for SZK in the previous section.

**Corollary 4.3** SZK is closed under (Karp) reductions. That is, if \(\Pi \in\text{SZK}\) and \(\Gamma\) reduces to \(\Pi\), then \(\Gamma \in\text{SZK}\).

**Proof:** By Corollary 4.2, \(\Pi\) has a security-parameterized statistical zero-knowledge proof. A statistical zero-knowledge proof for \(\Gamma\) can be obtained as follows: On input \(x\), the prover, verifier, and simulator run the security-parameterized proof for \(\Pi\) on input \((f(x), 1^{|x|})\), where \(f\) is the reduction from \(\Gamma\) to \(\Pi\). □
The security-parametrization property is necessary in the above proof, because an arbitrary reduc-

Corollary 4.4 ([Oka00, Thm. 2]) \(\text{SZK} \) is closed under complement, even for promise problems.

\textbf{Proof:} Let \( \Pi \) be any problem in \( \text{SZK} \). By Theorem 3.10 and Corollary 3.9, \( \overline{\Pi} \) reduces to SD, which is in \( \text{SZK} \). By Corollary 4.3, \( \overline{\Pi} \in \text{SZK} \). □

Before moving on to additional closure properties, we deduce the upper bounds of Fortnow [For89] and Aiello and Håstad [AH91] on the complexity of \( \text{SZK} \).

\textbf{Corollary 4.5 ([For89, AH91])} \( \text{SZK} \subseteq \text{AM} \cap \text{co-AM} \), where \( \text{AM} \) denotes the class of problems possessing constant-message interactive proofs.

\textbf{Proof:} Immediate from Corollaries 4.2 and 4.4. □

Above, we have seen that \( \text{SZK} \) satisfies a computational closure property (Corollary 4.3) and a boolean closure property (Corollary 4.4 [Oka00]). Now we will exhibit a stronger closure property, which can be viewed as both a computational one and a boolean one: given an arbitrary boolean formula whose atoms are statements about membership in any problem in \( \text{SZK} \), one can efficiently construct a statistical zero-knowledge interactive proof for its validity. Note that such a property does not follow immediately from the fact that a class is closed under intersection, union, and complementation, because applying these more than a constant number of times could incur a superpolynomial cost in efficiency, while we ask that the construction can be done efficiently with respect to the size of the formula. We achieve this by applying a construction of De Santis, Di Crescenzo, Persiano, and Yung [DDPY94] to STATISTICAL DIFFERENCE, and then appealing to the Completeness Theorem.

We begin with some definitions describing precisely what kind of boolean closure properties we will achieve. (Later, we will see how it can also be interpreted as closure under a certain class of polynomial-time reductions.) In order to deal with instances of promise problems that violate the promise, we will work with an extension of boolean algebra that includes an additional "ambiguous" value \( * \).

\textbf{Definition 4.6} A partial assignment to variables \( v_1, \ldots, v_k \) is a \( k \)-tuple \( \overline{\alpha} = (a_1, \ldots, a_k) \in \{0, 1, * \}^k \).

For a propositional formula (or circuit) \( \phi \) on variables \( v_1, \ldots, v_k \), the evaluation \( \phi(\overline{\alpha}) \) is recursively defined as follows:

\[
v_i(\overline{\alpha}) = a_i \quad \quad (\phi \land \psi)(\overline{\alpha}) = \begin{cases} 
1 & \text{if } \phi(\overline{\alpha}) = 1 \text{ and } \psi(\overline{\alpha}) = 1 \\
0 & \text{if } \phi(\overline{\alpha}) = 0 \text{ or } \psi(\overline{\alpha}) = 0 \\
* & \text{otherwise}
\end{cases}
\]

\[
(\neg \phi)(\overline{\alpha}) = \begin{cases} 
1 & \text{if } \phi(\overline{\alpha}) = 0 \\
0 & \text{if } \phi(\overline{\alpha}) = 1 \\
* & \text{if } \phi(\overline{\alpha}) = * 
\end{cases}
\]

\[
(\phi \lor \psi)(\overline{\alpha}) = \begin{cases} 
1 & \text{if } \phi(\overline{\alpha}) = 1 \text{ or } \psi(\overline{\alpha}) = 1 \\
0 & \text{if } \phi(\overline{\alpha}) = 0 \text{ and } \psi(\overline{\alpha}) = 0 \\
* & \text{otherwise}
\end{cases}
\]

Note that \( \phi(\overline{\alpha}) \) equals 1 (resp., 0) for some partial assignment \( \overline{\alpha} \), then \( \phi(\overline{\alpha}) \) also equals 1 (resp., 0) for every boolean \( \overline{\alpha} \) obtained by replacing every \( * \) in \( \overline{\alpha} \) with either a 0 or 1. The converse,
however, is not true: The formula $\phi = v \lor -v$ evaluates to 1 on every boolean assignment, yet is not 1 when evaluated at $\star$. Thus, the “law of excluded middle” $\phi \lor -\phi \equiv 1$ no longer holds in this setting. However, other identities in boolean algebra such as De Morgan’s laws (e.g. $-(\phi \lor \psi) \equiv -\phi \land -\psi$) do remain true.

**Definition 4.7** For a promise problem $\Pi$, the characteristic function of $\Pi$ is the map $\chi_\Pi : \{0, 1\}^* \rightarrow \{0, 1, \star\}$ given by

$$
\chi_\Pi(x) = \begin{cases} 
1 & \text{if } x \in \Pi_Y \\
0 & \text{if } x \in \Pi_N \\
\star & \text{otherwise}
\end{cases}
$$

**Definition 4.8** For any promise problem $\Pi$, we define a new promise problem $\Phi(\Pi)$ as follows:

$$
\Phi(\Pi)_Y = \{(\phi, x_1, \ldots, x_k) : \phi(\chi_\Pi(x_1), \ldots, \chi_\Pi(x_k)) = 1\}
$$

$$
\Phi(\Pi)_N = \{(\phi, x_1, \ldots, x_k) : \phi(\chi_\Pi(x_1), \ldots, \chi_\Pi(x_k)) = 0\},
$$

where $\phi$ is a $k$-ary propositional formula. $\text{Mon}(\Pi)$ is defined analogously, except that only monotone $\phi$ are considered.\(^\text{11}\)

In [DDPY94], it is shown that $\text{Mon}(L) \in \text{SZK}$ for any language $L$ which is random self-reducible, whose complement is self-reducible, or whose complement has a noninteractive statistical zero-knowledge proof. They also give statistical zero-knowledge proofs for some simple statements involving a random-self-reducible language and its complement. Damgård and Cramer [DC96] extend these results by showing that $\text{Mon}(L) \in \text{SZK}$ as long as $L$ or its complement has a 3-message public-coin statistical zero-knowledge proof, and also treat a larger class of monotone functions.

Our result holds for all of $\text{SZK}$ and for all boolean formulae, not just monotone ones:

**Theorem 4.9** For any promise problem $\Pi \in \text{SZK}$, $\Phi(\Pi) \in \text{SZK}$.

This theorem can be generalized to work for all boolean formulae whose atoms are statements about membership in any finite set of languages in $\text{SZK}$, but we omit the notationally cumbersome formal statement since it is immediate from the completeness of **Statistical Difference**.

Our proof of Theorem 4.9 is based heavily on the work of De Santis, Di Crescenzo, Persiano, and Yung [DDPY94], which constructs a statistical zero-knowledge proof for $\text{Mon}(L)$ for any random self-reducible language $L$. Their zero-knowledge proofs are constructed by producing two distributions which are either disjoint or identical, depending on whether or not the formula is true. Hence, their construction can be viewed as a reduction to extreme instances of $\text{SD}$, in which the thresholds are 1 and 0. Here, we begin by applying essentially the same construction to $\text{SD}$, but use the Direct Product, XOR, and the Polarization Lemmas of Section 3.2 to analyze it for all instances of $\text{SD}$ (rather than just the extreme ones). This proves that $\text{Mon}(\text{SD})$ is in $\text{SZK}$. Then, using the completeness of SD (Theorem 3.1) and closure under complement (Corollary 4.4 [Oka00]), we deduce the result for general (i.e. non-monotone) formulae and every promise problem in $\text{SZK}$.

As stated above, the main step in proving Theorem 4.9 is the following lemma.

**Lemma 4.10** $\text{Mon}(\text{SD}) \in \text{SZK}$.

\(^{11}\)In [DDPY94], only monotone formulae are treated. What they call $\Phi(L)$ is what we call $\text{Mon}(L)$.
Sample($\psi, b$)
- If $\psi = v_i$, sample $z \leftarrow D_b^i$.
- If $\psi = \tau \lor \mu$,
  - Sample $z_1 \leftarrow \text{Sample}(\tau, b)$;
  - Sample $z_2 \leftarrow \text{Sample}(\mu, b)$;
  - Let $z = (z_1, z_2)$.
- If $\psi = \tau \land \mu$,
  - Choose $c, d \in \mathbb{R}\{0, 1\}$ subject to $c \oplus d = b$;
  - Sample $z_1 \leftarrow \text{Sample}(\tau, c)$;
  - Sample $z_2 \leftarrow \text{Sample}(\mu, d)$;
  - Let $z = (z_1, z_2)$.
Output $z$.

Figure 1:

**Proof:** For intuition, consider two instances of statistical difference $(C_0, C_1)$ and $(D_0, D_1)$, both of which have statistical difference very close to 1 or very close to 0 (which can be achieved by the Polarization Lemma). Then $(C_0 \oplus D_0, C_1 \oplus D_1)$ will have statistical difference very close to 1 if either of the original statistical differences is very close to 1 and will have statistical difference very close to 0 otherwise. Thus, this Direct Product operation represents OR. Similarly, the XOR operation in Proposition 3.6 represents AND. We will recursively apply these constructions to obtain a reduction from Mon(SD) to SD. By closure under reductions (Corollary 4.3, Lemma 4.10 will follow.

Let $w = (\phi, (C_0^0, C_1^0), \ldots, (C_0^k, C_1^k))$ be an instance of Mon(SD) and let $n = |w|$. By applying the Polarization Lemma (Lemma 3.3), we can construct in polynomial time pairs of circuits $(D_0^0, D_1^0), \ldots, (D_0^k, D_1^k)$ such that the statistical difference between $D_0^i$ and $D_1^i$ is greater than $1 - 2^{-n}$ if $(C_0^i, C_1^i) \in \text{SD}_Y$ and is less than $2^{-n}$ if $(C_0^i, C_1^i) \in \text{SD}_X$.

Consider the randomized recursive procedure Sample($\psi, b$) in Figure 1 which takes a subformula $\psi$ of $\phi = \phi(v_1, \ldots, v_n)$ and a bit $b \in \{0, 1\}$ as input. Executing Sample($\phi, b$) for $b \in \{0, 1\}$ takes time polynomial in $n$, because the number of recursive calls is equal to the number of subformulae of $\phi$. For a subformula $\psi$ of $\phi$, define

$$\text{Dif}(\psi) = \|\text{Sample}(\psi, 0) - \text{Sample}(\psi, 1)\|.$$

Then we can prove the following about Dif:

**Claim 4.11** Let $\bar{\psi} = (\chi_{\text{SD}}(C_0^1, C_1^1), \ldots, \chi_{\text{SD}}(C_0^k, C_1^k))$. For every subformula $\psi$ of $\phi$, we have:

- $\psi(\bar{\psi}) = 1 \Rightarrow \text{Dif}(\psi) > 1 - |\psi|2^{-n}$
- $\psi(\bar{\psi}) = 0 \Rightarrow \text{Dif}(\psi) < |\psi|2^{-n}$

Note that nothing is claimed when $\psi(\bar{\psi}) = \ast$.

**Proof of claim:** The proof of the claim is by induction on subformulae $\psi$ of $\phi$. It holds for atomic subformulae (i.e. the variables $v_i$) by the properties of the $D_b^i$'s.

**Case 1:** $\psi = \tau \lor \mu$. If $\psi(\bar{\tau}) = 1$, then either $\tau(\bar{\psi}) = 1$ or $\mu(\bar{\psi}) = 1$. Without loss of generality, say $\tau(\bar{\psi}) = 1$. Then, by Fact 2.4 and induction,

$$\text{Dif}(\psi) \geq \text{Dif}(\tau) > 1 - |\tau|2^{-n} > 1 - |\psi|2^{-n}.$$
If \( \psi(\pi) = 0 \), then \( \tau(\pi) = \mu(\pi) = 0 \). By Fact 2.3 and induction,

\[
\text{Dif}(\psi) \leq \text{Dif}(\tau) + \text{Dif}(\mu) < |\tau|2^{-n} + |\mu|2^{-n} \leq |\psi|2^{-n}.
\]

**Case 1:** \( \psi = \tau \land \mu \). By Proposition 3.6, \( \text{Dif}(\psi) = \text{Dif}(\tau) \cdot \text{Dif}(\mu) \). If \( \psi(\pi) = 1 \), then, by induction,

\[
\text{Dif}(\psi) \geq (1 - |\tau|2^{-n})(1 - |\mu|2^{-n}) > 1 - (|\tau| + |\mu|)2^{-n} \geq 1 - |\psi|2^{-n}.
\]

If \( \psi(\pi) = 0 \), then, without loss of generality, say \( \tau(\pi) = 0 \). By induction,

\[
\text{Dif}(\psi) \leq \text{Dif}(\tau) \leq |\psi|2^{-n}.
\]

Now, let \( A \) and \( B \) be the circuits which sample from the distributions \( \text{Sample}(\phi, 0) \) and \( \text{Sample}(\phi, 1) \), respectively. (The random bits each procedure uses are the inputs to the circuits). By the above claim, \( \|A - B\| > 1 - n2^{-n} > 2/3 \) if \( \phi(\pi) = 1 \), and \( \|A - B\| < n2^{-n} < 1/3 \) if \( \phi(\pi) = 0 \). In other words, the construction of \( A \) and \( B \) from \( w \) is a reduction from \( \text{Mon(SD)} \) to \( \text{SD} \). This reduction can be computed in polynomial time because \( \text{Sample} \) runs in polynomial time. Thus, by Corollary 4.3, \( \text{Mon(SD)} \in \text{SZK} \). ■

Now it is straightforward to deduce Theorem 4.9.

**Proof:** Let \( \Pi \) be any promise problem in \( \text{SZK} \). By closure under complement (Corollary 4.4 [Oka00]) and the completeness of \( \text{SD} \) (Theorem 3.1), both \( \Pi \) and \( \overline{\Pi} \) reduce to \( \text{SD} \). Let \( f \) and \( g \) be these reductions, respectively. Now, let \( (\phi, x_1, \ldots, x_k) \) be any instance of \( \Phi(\Pi) \), where \( \phi = \phi(v_1, \ldots, v_k) \). Use De Morgan’s laws to propagate all negations of \( \phi \) to its variables. Now replace all occurrences of the literal \( \neg v_i \) with a new variable \( w_i \). Let \( \psi(v_1, \ldots, v_k, w_1, \ldots, w_k) \) be the resulting (monotone) formula. It is clear that

\[
(\phi, x_1, \ldots, x_k) \mapsto (\psi, f(x_1), \ldots, f(x_k), g(x_1), \ldots, g(x_k))
\]

is a reduction from \( \Phi(\Pi) \) to \( \text{Mon(SD)} \). Since \( \text{Mon(SD)} \in \text{SZK} \) (Lemma 4.10) and \( \text{SZK} \) is closed under reductions (Corollary 4.3), Theorem 4.9 follows. ■

Theorem 4.9 can be also viewed as demonstrating that \( \text{SZK} \) is closed under a type of polynomial-time reducibility, which is formalized by the following two definitions.

**Definition 4.12** (truth-table reduction [LLS75]): We say a promise problem \( \Pi \) truth-table reduces to a promise problem \( \Gamma \) if there exists a (deterministic) polynomial-time computable function \( f \), which on input \( x \) produces a tuple \( (y_1, \ldots, y_k) \) and a boolean circuit \( C \) (with \( k \) input gates) such that

\[
x \in \Pi_Y \Rightarrow C(\chi_{\Gamma}(y_1), \ldots, \chi_{\Gamma}(y_k)) = 1
\]

\[
x \in \Pi_N \Rightarrow C(\chi_{\Gamma}(y_1), \ldots, \chi_{\Gamma}(y_k)) = 0
\]

In other words, a truth-table reduction for promise problems is a nonadaptive Cook reduction which is allowed to make queries which violate the promise, but still must have an unambiguous output (in the strong sense formalized by Definition 4.6). We further consider the case where we restrict the complexity of computing the output of the reduction from the queries.
Definition 4.13 (NC^1 truth-table reductions): A truth-table reduction \( f \) between promise problems is an NC^1 truth-table reduction if the circuit \( C \) produced by the reduction on input \( x \) has depth bounded by \( c_f \log |x| \), where \( c_f \) is a constant independent of \( x \).

With these definitions, we can restate Theorem 4.9 as follows:

Corollary 4.14 SZK is closed under NC^1 truth-table reductions.

Proof: Any circuit of size \( s \) and depth \( d \) can be efficiently “unrolled” into a formula of size \( 2^d \cdot s \). Hence, an NC^1 truth-table reduction from \( \Gamma \) to \( \Pi \) gives rise to a Karp reduction from \( \Gamma \) to \( \Phi(\Pi) \). Since SZK is closed under \( \Phi(\cdot) \) and Karp reductions, it is also closed under NC^1 truth-table reductions.

It would be interesting to prove that SZK is closed under general truth-table reductions (or, even better, adaptive Cook reductions), or give evidence that this is not the case.

4.3 Knowledge complexity

Knowledge complexity [GMR89, GP99] is a generalization of zero knowledge which attempts to quantify how much a verifier learns from an interactive proof. A number of different measures have been proposed to accomplish this, most of which are based on the intuition that a verifier gains at most \( k \) bits of “knowledge” from an interaction if it can simulate the interaction with at most \( k \) bits of “help”. Below we give terse definitions of the variants we consider. The first three definitions come from [GP99], and the last comes from [ABV95]. Let \( (P, V) \) be an interactive proof system for a promise problem \( \Pi \). Then the knowledge complexity of \( (P, V) \) in various senses is defined as follows:

- **Hint sense**: We say that \( (P, V) \) has perfect (resp., statistical) knowledge complexity \( k(n) \) in the hint sense if there exists a PPT simulator \( S \) and a hint function \( h: \Pi_Y \to \{0,1\}^* \) such that for all \( x \in \Pi_Y \), \( |h(x)| = k(|x|) \) and \( \| S(x, h(x)) - \text{View}_{P,V}(x) \| \) is 0 (resp., is bounded by a negligible function of \( |x| \)).

- **Strict oracle sense**: \( (P, V) \) is said to have perfect (resp., statistical) knowledge complexity \( k(n) \) in the strict oracle sense if there exists a PPT oracle-machine \( S \) and an oracle \( O \) such that on every input \( x \in \Pi_Y \), \( S \) queries \( O \) at most \( k(|x|) \) times and \( \| S^O(x) - \text{View}_{P,V}(x) \| \) is 0 (resp., is bounded by a negligible function of \( |x| \)).

- **Oracle sense**: \( (P, V) \) is said to have perfect (resp., statistical) knowledge complexity \( k(n) \) in the oracle sense if there exists a PPT oracle-machine \( S \) and an oracle \( O \) such that on every input \( x \in \Pi_Y \), \( S \) queries \( O \) at most \( k(|x|) \) times, \( S \) outputs ‘fail’ with probability at most 1/2, and \( \| S^O(x) - \text{View}_{P,V}(x) \| \) is 0 (resp., is bounded by a negligible function of \( |x| \)), where \( S^O(x) \) denotes the output distribution of \( S \) conditioned on non-failure.

- **Average oracle sense**: \( (P, V) \) has perfect (resp., statistical) knowledge complexity \( k(n) \) in the average oracle sense if there exists a PPT oracle-machine \( S \) and an oracle \( O \) such that for every input \( x \in \Pi_Y \), the average number of queries \( S \) makes to \( O \) is at most \( k(|x|) \) and \( \| S^O(x) - \text{View}_{P,V}(x) \| \) is 0 (resp., is bounded by a negligible function of \( |x| \)).
• **Entropy sense:** \((P, V)\) has perfect (resp., statistical) knowledge complexity \(k(n)\) in the entropy sense if there exists a PPT oracle-machine \(S\), an oracle \(O\), and a PPT oracle-simulator \(A\) such that for all \(x \in \Pi_Y\), 
\[ E_R[\log P_x(R)^{-1}] \leq k(\|x\|), \]
where \(P_x(R) = \Pr[\rho, A(x, R; \rho) = S^O(x; R)]\) and \(\|S^O(x) - \text{View}_{P, Y}(x)\|\) is 0 (resp., is bounded by a negligible function of \(\|x\|\)).

The knowledge complexity (in some specified sense) of a promise problem \(\Pi\) is \(k(n)\) if there exists an interactive proof system \((P, V)\) for \(\Pi\) achieving negligible error probability in both the completeness and soundness conditions such that the knowledge complexity of \((P, V)\) is \(k(n)\). The class of languages possessing perfect knowledge complexity \(k(n)\) in the hint, strict oracle, average oracle, and entropy senses are denoted by \(\text{PKC}_{\text{hint}}(k(n))\), \(\text{PKC}_{\text{strict}}(k(n))\), \(\text{PKC}_{\text{avg}}(k(n))\), and \(\text{PKC}_{\text{ent}}(k(n))\), respectively. Statistical knowledge complexity is denoted by \(\text{SKC}(k(n))\) with the appropriate subscript.

A Collapse for the Hint Sense

Our first result about knowledge complexity is that the \(\text{SKC}_{\text{hint}}\) hierarchy collapses by logarithmic additive factors. Previously, Goldreich and Petrank [GP99] have shown that \(\text{SKC}_{\text{hint}}(\text{poly}(n)) \subset \text{AM}\) and \(\text{SKC}_{\text{hint}}(O(\log(n))) \subset \text{co-AM}\); the second of these results can be derived immediately from our result and the result \(\text{SZK} \subset \text{co-AM}\) (Corollary 4.5 [For89, AH91]).

**Theorem 4.15** For any polynomially bounded function \(k(n)\),

\[ \text{SKC}_{\text{hint}}(k(n) + \log n) = \text{SKC}_{\text{hint}}(k(n)). \]

For intuition, consider the case that \(k(n) = 0\). Loosely speaking, if the verifier is given the hint along with the input (with the “promise” that the hint is correct), then the original proof system becomes zero knowledge, so we can apply the results of the previous section. By the boolean closure properties established in Theorem 4.9, we can take the “union over all possible hints” (there are only polynomially many of them) without leaving \(\text{SZK}\).

In order to turn this intuition into a proof, we first show that knowledge complexity in the hint sense can be characterized in terms of zero-knowledge promise problems, so that questions about the \(\text{SKC}_{\text{hint}}\) hierarchy are reduced to questions about statistical zero knowledge. This is equivalence is obtained by providing the hint along with the input and “promising” that the hint is correct.

**Lemma 4.16** Let \(k(n)\) be any polynomially bounded function. Then \(\Pi \in \text{SKC}_{\text{hint}}(k(n))\) (resp., \(\text{PKC}_{\text{hint}}(k(n))\)) iff there exists a promise problem \(\Gamma \in \text{SZK}\) (resp., \(\text{PZK}\)) such that

1. \(x \in \Pi_Y \Rightarrow \text{there exists a such that } |a| = k(\|x\|)\) and \((x, a) \in \Gamma_Y\), and
2. \(x \in \Pi_N \Rightarrow \text{for all } a, (x, a) \in \Gamma_N\).

**Proof:** We only give the proof for statistical knowledge complexity and zero knowledge; the perfect case is identical.

\[ \Rightarrow \text{ Let } \Pi \text{ be a promise problem in } \text{SKC}_{\text{hint}}(k(n)) \text{ and let } h : \Pi_Y \to \{0, 1\}^*. \text{ be a hint function corresponding to an appropriate interactive proof system and simulator for } \Pi. \text{ Consider the following promise problem } \Gamma:\]

\[
\Gamma_Y = \{(x, h(x)) : x \in \Pi_Y\} \\
\Gamma_N = \{(x, a) : x \in \Pi_N\}
\]
By using the protocol and simulator for Π, we see that Γ ∈ SZK (the verifier and prover for Γ should ignore the second component, whereas the simulator uses it as a hint.) It is clear that Γ satisfies the other conditions of Lemma 4.16.

⇐ Let Γ ∈ SZK be the promise problem satisfying the stated conditions. Let h : ΠY → {0, 1}∗ be any function such that for all x ∈ ΠY,

1. |h(x)| = k(|x|),
2. (x, h(x)) ∈ ΓY.

(Such a function is guaranteed by Condition 1.) We now give a proof system for Π of knowledge complexity k(n). On input x, the prover gives the verifier h(x) in the first step, and then they execute the protocol for Γ on (x, h(x)). The completeness and soundness of this protocol follow from the properties of the Γ proof system. This proof system is easily seen to have knowledge complexity k(n) in the hint sense, using the hint h(x) with the zero-knowledge simulator for Γ.

We now prove Theorem 4.15.

Proof: Let Π be a problem in SKChint(k(n) + log n) and let Γ be the promise problem guaranteed by Lemma 4.16. By Theorem 4.9, Φ(Γ) ∈ SZK. Now consider a different, but related promise problem Γ′, defined by

Γ′ = \{(x, a) : \text{there exists } b \text{ such that } |b| = \log |x| \text{ and } (x, ab) ∈ ΓY\}
Γ′ = \{(x, a) : \text{for all } b, (x, ab) ∈ ΓN\} = \{(x, a) : x ∈ ΠN\}.

For any string x, let b1, . . . , bn be all strings of length log |x|, and let C be the circuit of depth O(log |x|) computing the function φ(v1, . . . , vn) = \bigvee i vi. The relationship between Γ and Γ′ above implies that

(x, a) \mapsto (φ(x, ab1), . . . , (x, abn))

is an NC1 truth-table reduction from Γ′ to Γ. Since SZK is closed under such reductions (Corollary 4.14), we conclude that Γ′ ∈ SZK.

Now, x ∈ ΠY, then there exists an a of length k(|x|) + log(|x|) such that (x, a) ∈ ΓY. Taking a′ to be the first k(|x|) bits of a, we see that there exists an a′ of length k(|x|) such that (x, a′) ∈ ΓY. Moreover, if x ∈ ΠN, then for all a, (x, a) ∈ ΓN. Thus, by Lemma 4.16, we conclude that Π ∈ SKChint(k(n)).

The Perfect Knowledge Complexity of SZK

The next theorem establishes tighter bounds on the perfect knowledge complexity of SZK. Aiello, Bellare, and Venkatesan [ABV95] have previously demonstrated that every language in SZK has perfect knowledge complexity n−ω(1) (resp., 1 + n−ω(1)) in the entropy (resp. average oracle) sense. Our results improve on these bounds, although the results of [ABV95] also apply to cheating-verifier classes and ours do not. Goldreich, Ostrovsky, and Petrank [GOP98] show that SZK has logarithmic perfect knowledge complexity in the oracle sense, so our results are incomparable to theirs. Our result for the strict oracle sense is the first that we know of.
Theorem 4.17

1. For every polynomial-time computable $m(n) = \omega(\log n)$, $\text{SZK} \subset \text{PKC}_{\text{strict}}(m(n))$.

2. $\text{SZK} \subset \text{PKC}_{\text{avg}}(1 + 2^{-n})$.

3. $\text{SZK} = \text{PKC}_{\text{ent}}(2^{-n})$.

Corollary 4.2 tells us that every problem in $\text{SZK}$ has a simple two-message proof system like the SD proof system of Section 3.3. Thus, in order to measure the perfect knowledge complexity of $\text{SZK}$ and prove Theorem 4.17, it suffices to analyze this protocol. Intuitively, since the prover is only sending the verifier one bit and this bit is almost always a value the verifier knows, the knowledge complexity of this protocol should be extremely small. However, this argument does not suffice, because the knowledge complexity of a problem $\Pi$ is determined only by proof systems for $\Pi$ which achieve negligible error probability in both the completeness and soundness conditions. We can overcome this difficulty by performing $\omega(\log n)$ parallel repetitions.

Proof: Let $\Pi$ be any problem in $\text{SZK}$ and let $(P, V)$ be the proof system for $\Pi$ constructed in Corollary 4.2 (from the SD proof system of Section 3.3) with the security parameter set to $k = 4n$ (so the completeness error is $2^{-4n}$). Let $m = m(n)$ be any function computable in time $\text{poly}(n)$ such that $\omega(\log n) \leq m \leq n$. Consider the proof system $(P', V')$ obtained by $m$ parallel repetitions of $(P, V)$; this has negligible completeness and soundness errors. We now analyze its perfect knowledge complexity.

1. The prover sends at most $m$ bits to the verifier on inputs of length $n$, so the perfect knowledge complexity of this protocol in the strict oracle sense is bounded by $m$.

2. A perfect simulator for $(P', V')$ can be obtained as follows: On input $x$ of length $n$, the simulator runs $V(x)$ for $m$ times independently and queries the oracle once to find out if any of these runs would result in an incorrect prover response. If the oracle replies yes, the simulator queries the oracle $m$ more times to find out which runs would result in an incorrect response. The simulator then outputs the random coins used for running $V$ and the appropriate prover responses.

In each subprotocol, the prover gives an incorrect response with probability at most $2^{-4n}$. Thus, the simulator has to query the oracle for more than one bit with probability at most $m2^{-4n}$. Thus, on average, the simulator queries the oracle for at most $1 + m2^{-4n} < 1 + 2^{-n}$ bits.

3. Let $S$ be the simulator for $(P', V')$ which simply simulates $V'$ and queries the oracle $O$ for all prover responses. One possible oracle simulator would assume that the prover is correct in all subprotocols. Unfortunately, this gives $1/P_x(R) = \infty$ for some $R$ and yields infinite knowledge complexity. Thus, we instead have our oracle simulator $A$ assume that the prover is right in each subprotocol independently with probability $1 - \delta$, where $\delta = 2^{-2n}$. Thus, $P_x(R) = (1 - \delta)^k\delta^{m-k}$, if $R$ is a set of random coins for $V'$ (equivalently $S$, since $S$ mimics $V'$) which would elicit a correct prover response in exactly $k$ of the subprotocols. Let $\epsilon$ be

\[ \text{2-}\Omega(n) \] in these results can be improved to $2^{-\Theta(n^k)}$ for any constant $k$ by polarizing with security parameter $n^k$ instead of $n$ in the SD proof system of Section 3.3.
the probability that the prover is incorrect in an individual subprotocol. Then, \( \epsilon \leq \delta^2 \), and we have

\[
E_R \left[ \log \frac{1}{P_x(R)} \right] = \sum_{k=0}^{m} \binom{m}{k} e^{m-k}(1-\epsilon)^k \log \left( \frac{1}{(1-\delta)^k \delta^{m-k}} \right) \\
= \left( \log \frac{1}{\delta^m} \right) \sum_{k=0}^{m} \binom{m}{k} e^{m-k}(1-\epsilon)^k + \left( \log \frac{\delta}{1-\delta} \right) \sum_{k=0}^{m} \binom{m}{k} e^{m-k}(1-\epsilon)^k \\
= \log \frac{1}{\delta^m} + m(1-\epsilon) \left( \log \frac{\delta}{1-\delta} \right) \\
\leq m \left( \log \frac{1}{1-\delta} + \delta^2 \log \frac{1}{\delta} \right) \\
\leq 2m\delta < 2^{-n}
\]

for sufficiently large \( n \). Note that the third equality above follows from the identity \( \binom{m}{k} = m(m-1) \).

The opposite inclusion follows from the result of [ABV95] that \( \text{PKC}_{\text{ent}}(\neg(n)) \subseteq \text{SZK} \) for any negligible function \( \neg(n) \).

### 4.4 Reversing statistical difference

By the completeness of SD (Theorem 3.1) and SZK’s closure under complement (Corollary 4.4), it follows that \( \overline{\text{SD}} \) reduces to SD. This is equivalent to the following surprising result:

**Corollary 4.18 (Reversal Mapping)** There is a polynomial-time computable function that maps pairs of circuits \((C_0, C_1)\) to pairs of circuits \((D_0, D_1)\) such that

\[
\|C_0 - C_1\| < 1/3 \quad \Rightarrow \quad \|D_0 - D_1\| > 2/3 \\
\|C_0 - C_1\| > 2/3 \quad \Rightarrow \quad \|D_0 - D_1\| < 1/3.
\]

That is, SD reduces to \( \overline{\text{SD}} \).

This corollary motivated our search for a more explicit description of such a mapping. By extracting ideas used in the transformations of statistical zero-knowledge proofs given in [Oka00] and [SV97], we obtained the description of this transformation given below.

**The Construction.** Let \((C_0, C_1)\) be any pair of circuits and let \( n = |(C_0, C_1)| \). By the Polarization Lemma (Lemma 3.3), we can produce in polynomial time a pair of circuits \((C_0, C_1)\) such that

\[
\|C_0 - C_1\| < 1/3 \quad \Rightarrow \quad \|\overline{C_0} - \overline{C_1}\| > 1 - 2^{-n} \\
\|C_0 - C_1\| > 2/3 \quad \Rightarrow \quad \|\overline{C_0} - \overline{C_1}\| < 2^{-n}
\]

30
Let $q = \text{poly}(n)$ be the number of input gates of $\tilde{C}_0$ and $\tilde{C}_1$ (w.l.o.g. we may assume they have the same number) and let $\ell = \text{poly}(n)$ be the number of output gates. For notational convenience, let $R = \{0,1\}^q$ and $L = \{0,1\}^{\ell}$. Let $m = n^3q^2$ and define a new distribution $\tilde{C} : \{0,1\}^m \times R^m \rightarrow L^m$ as follows:

$$\tilde{C}(\tilde{b}, \tilde{r}) = (\tilde{C}_{b_1}(r_1), \ldots, \tilde{C}_{b_m}(r_m)).$$

We use the notation $\tilde{z} \leftarrow \tilde{C}$ to denote $\tilde{z}$ chosen according to $\tilde{C}$, i.e. select $\tilde{b}$ and $\tilde{r}$ uniformly and let $\tilde{z} = \tilde{C}(\tilde{b}, \tilde{r})$.

Let $\mathcal{H}$ be a 2-universal family of hash functions from $\{0,1\}^m \times R^m \times L^m$ to $S = \{0,1\}^{(q+1)m - 2\Delta - n}$, where $\Delta = \sqrt{nmq^2} = m/n$. We can now describe the new distributions:

| $D_0$: Choose $(\tilde{b}, \tilde{r}) \in_R \{0,1\}^m \times R^m$, $\tilde{y} \leftarrow \tilde{C}$, and $h \in_R \mathcal{H}$. Output $(\tilde{C}(\tilde{b}, \tilde{r}), \tilde{b}, h(\tilde{b}, \tilde{r}, \tilde{y}))$. |
| $D_1$: Choose $(\tilde{b}, \tilde{r}) \in_R \{0,1\}^m \times R^m$, $h \in_R \mathcal{H}$, and $s \in_R S$. Output $(\tilde{C}(\tilde{b}, \tilde{r}), \tilde{b}, h, s)$. |

The important things to note about these distributions are that $\tilde{b}$ is part of the output, and that $D_0$ and $D_1$ only differ in the last component, where $D_0$ has the value of the hash function and $D_1$ has a truly random element of $S$. Also note that the size of $S$ is chosen to be $|\{0,1\}^m \times R^m|/2^{2\Delta + n}$, which is essentially $|\{0,1\}^m \times R^m|$, scaled down by a “slackness” factor of $2^{2\Delta + n}$. The introduction of the sample $\tilde{y}$ in $D_0$ may at first seem superfluous; we explain below.

**Intuition.** For intuition, consider the case that $\tilde{C}$ is a flat distribution; that is, for every $\tilde{z} \in \text{range}(\tilde{C})$, the size of the preimage set $|\{\tilde{b}, \tilde{r} : \tilde{C}(\tilde{b}, \tilde{r}) = \tilde{z}\}|$ is the same value $N$. Then the range of $\tilde{C}$ has size $|\{0,1\}^m \times R^m|/N = 2^{(q+1)m}/N$. So, in $D_0$, conditioned on a value for $\tilde{C}(\tilde{b}, \tilde{r})$, the triple $(\tilde{b}, \tilde{r}, \tilde{y})$ is selected uniformly from a set of size $2^{(q+1)m}$. Since this is much greater than $|S|$, the Leftover Hash Lemma of [HILL99] implies that conditioned on any value for the first component of $D_0$, the last two components $(h, h(\tilde{b}, \tilde{r}, \tilde{y}))$ are distributed close to the uniform distribution on $\mathcal{H} \times S$, which is the distribution that $D_1$ has in its last two components. Thus, if their second components were missing, $D_0$ and $D_1$ would be statistically close. Now, consider the case that $\|\tilde{C}_0 - \tilde{C}_1\| \approx 1$. Then $\tilde{b}$ is essentially “determined” by $\tilde{C}(\tilde{b}, \tilde{r})$. So the presence of $\tilde{b}$ can be ignored, and the above argument says that $D_0$ and $D_1$ are statistically very close. Now, consider the case that $\|\tilde{C}_0 - \tilde{C}_1\| \approx 0$. Then $\tilde{b}$ is essentially “unrestricted” by $\tilde{C}(\tilde{b}, \tilde{r})$. Since there are $2^m$ choices for $\tilde{b}$, conditioning on $\tilde{b}$ in addition to $\tilde{C}(\tilde{b}, \tilde{r})$, cuts the number of triples $(\tilde{b}, \tilde{r}, \tilde{y})$ down from $2^{m(q+1)}$ to roughly $2^{m(q+1)}/2^m$. Since $2^{m(q+1)}/2^m$ is much smaller than $|S|$, $h(\tilde{b}, \tilde{r}, \tilde{y})$ will cover only a small fraction of $|S|$ and thus will be far from uniform (conditioned on values for $\tilde{C}(\tilde{b}, \tilde{r}), \tilde{b}$, and $h$).

**Direct Proof of Corollary 4.18.** First we will argue that $\tilde{C}$ is close to being flat (in a particular sense), so that we can apply arguments like those given above. The fact that $\tilde{C}$ is close to flat will follow from the fact that it is composed of many independent, identically distributed random

---

13 Here we see the importance of $\tilde{y}$. Without $\tilde{y}$, conditioned on some value of $\tilde{C}(\tilde{b}, \tilde{r})$, the pair $(\tilde{b}, \tilde{r})$ would be selected uniformly from a space of size $N$. If we were only hashing this pair, for the distribution $h(\tilde{b}, \tilde{r})$ to be uniform by the Leftover Hash Lemma, $S$ would have to be chosen so that $|S| \ll N$. The value of $N$, however, depends on the inner workings of the circuit $C$, and is in general unknown. By including $\tilde{y}$, which comes uniformly from a space of size $2^{m(q+1)}N$, we balance the arguments to $h$ so that they come from a space of size $2^{m(q+1)n}$, a known quantity. This use of “dummy” samples to form a space whose size is known is the “complementary usage of messages” technique of Okamoto [Oka06].
variables. This is a form of the Asymptotic Equipartition Property commonly used in Information Theory (cf., [CT91]).

For $\vec{z} \in L^m$, we say the weight of $\vec{z}$ is the logarithm of the size of the preimage set of $\vec{z}$. Formally, let $\text{wt}(\vec{z}) = \log_2 \{|(b, r) : \vec{C}(b, r) = \vec{z}\}$. Let $w$ be the expected weight of an image, i.e. $w = E_{\vec{z} \sim \vec{C}} [\text{wt}(\vec{z})]$. Then we can show the following:

**Lemma 4.19** \( \Pr_{\vec{z} \sim \vec{C}} [\text{wt}(\vec{z}) - w > \Delta] < 2^{-\Omega(n)} \).

This is a quantitative version of the standard Asymptotic Equipartition Property of Information Theory (cf., [CT91]).

**Proof:** For $z \in L$, let $\text{wt}_0(z) = \log_2 \{|(b, r) : \vec{C}_b(r) = z\}$. Then, for $\vec{z} \in L^m$, $\text{wt}(\vec{z}) = \text{wt}_0(z_1) + \cdots + \text{wt}_0(z_m)$. Observe that when $\vec{z}$ is selected according to $\vec{C}$, $z_1, \ldots, z_m$ are independent and identically distributed. Moreover, for any $z \in L$, $0 \leq \text{wt}_0(z) \leq q$. So, by the Hoeffding inequality [Hof95, Sec. 7.2.1], we have

$$
\Pr_{\vec{z} \sim \vec{C}} [\text{wt}(\vec{z}) - w > \Delta] < 2e^{-2\Delta^2/mq^2} = 2e^{-2n}.
$$

It will be convenient to eliminate those $\vec{z} \in L^m$ that have weight far above or below the mean. Let $T = \{(b, r) : |\text{wt}(\vec{C}(b, r)) - w| \leq \Delta\}$, which we will call the set of *typical pairs* $(\vec{b}, \vec{r})$. The above Lemma says that $|T| \geq (1 - 2^{-\Omega(n)})|\{0, 1\}^m \times R^m|$. Thus $|T - \{0, 1\}^m \times R^m| \leq 2^{-\Omega(n)}$, where for simplicity of notation, we let the name of a set also refer to the uniform distribution on the same set. Define $\vec{C}^t$ to be the distribution obtained by selecting $(\vec{b}, \vec{r}) \leftarrow T$ and outputting $\vec{C}(\vec{b}, \vec{r})$. Then, since $\vec{C}$ is a function, Fact 2.4 tells us that $\|\vec{C} - \vec{C}^t\| = 2^{-\Omega(n)}$. Similarly, we define variants of $D_0$ and $D_1$ that sample from $T$ instead of $\{0, 1\}^m \times R^m$:

\[
\begin{align*}
D_0': \text{Let } (\vec{b}, \vec{r}) &\in_R T, \vec{y} \leftarrow \vec{C}^t, \text{ and } h \in_R H. \text{ Output } (\vec{C}(\vec{b}, \vec{r}), \vec{b}, h, h(\vec{b}, \vec{r}, \vec{y})). \\
D_1': \text{Let } (\vec{b}, \vec{r}) &\in_R T, h \in_R H, \text{ and } s \in_R S. \text{ Output } (\vec{C}(\vec{b}, \vec{r}), \vec{b}, h, s).
\end{align*}
\]

Since $D_0'$ (respectively $D_1'$) is a randomized procedure applied to two (resp., one) independent samplings from $T$, Fact 2.4 tells us that $\|D_0 - D_0'\| = 2^{-\Omega(n)}$ (resp., $\|D_1 - D_1'\| = 2^{-\Omega(n)}$). Hence, it suffices to prove that these modified distributions have the properties we want in each case. For the case when $C_0$ and $C_1$ are statistically far, we prove the following claim:

**Claim 4.20** If $\|\vec{C}_0 - \vec{C}_1\| > 1 - 2^{-n}$, then $\|D_0 - D_1'\| < 2^{-\Omega(n)}$.

**Proof of claim:** First we formalize the idea that $\vec{b}$ is “determined” by $\vec{C}$. Define $f : L \rightarrow \{0, 1\}$ by

$$
f(z) = \begin{cases} 
0 & \text{if } \Pr[\vec{C}_0 = z] > \Pr[\vec{C}_1 = z] \\
1 & \text{otherwise}
\end{cases}
$$

In other words, $f$ is exactly the prover strategy from the proof system for Statistical Difference given in Section 3.3. The completeness of that proof system (Lemma 3.7)
says that $\Pr_{b,r}[f(\tilde{C}_b(r)) = b] > 1 - 2^{-n}$. Now define $\tilde{f} : L^m \to \{0, 1\}^m$ by $\tilde{f}(\bar{z}) = (f(z_1), \ldots, f(z_m))$. Then
\[ \Pr_{\tilde{b},\tilde{r}}[\tilde{f}(\tilde{C}(\tilde{b},\tilde{r})) = \tilde{b}] > (1 - 2^{-n})^m = 1 - 2^{-\Omega(n)}. \]

Since $T$ is a $1 - 2^{-\Omega(n)}$ fraction of $\{0, 1\}^m \times R^m$, the same is true when $(\tilde{b},\tilde{r})$ is selected uniformly from $T$. Thus, if we define:

\begin{itemize}
  \item $D''_0$: Let $(\tilde{b},\tilde{r}) \in_R T$, $\tilde{y} \leftarrow \tilde{C}'$, and $h \in_R \mathcal{H}$. Output $(\tilde{C}(\tilde{b},\tilde{r}), \tilde{f}(\tilde{C}(\tilde{b},\tilde{r})), h, h(\tilde{b},\tilde{r},\tilde{y}))$.
  \item $D''_1$: Let $(\tilde{b},\tilde{r}) \in_R T$, $h \in_R \mathcal{H}$, and $s \in_R S$. Output $(\tilde{C}(\tilde{b},\tilde{r}), \tilde{f}(\tilde{C}(\tilde{b},\tilde{r})), h, s)$.
\end{itemize}

Then, $\|D''_0 - D''_1\| = 2^{-\Omega(n)}$ and $\|D'_1 - D''_1\| = 2^{-\Omega(n)}$. So it suffices to show that $\|D'_0 - D'_1\| = 2^{-\Omega(n)}$. Since the first components of $D'_0$ and $D''_1$ are identically distributed and the second components are determined by the first ones, it suffices to show (by Fact 2.5) that, conditioned on any value for the first coordinate, the third and fourth components have statistical difference $2^{-\Omega(n)}$. This will follow from the Leftover Hash Lemma [HILL99]:

**Lemma 4.21 (Leftover Hash Lemma [HILL99]):** Let $\mathcal{H}$ be a family of 2-universal hash functions from $D$ to $S$. Let $X$ by a probability distribution on $D$ such that for all $x \in D$, $\Pr[X = x] \leq \epsilon/|S|$. Then the following two distributions have statistical difference at most $\epsilon^{1/3}$.

1. Choose $x \leftarrow X$, $h \in_R \mathcal{H}$. Output $(h, h(x))$.
2. Choose $h \in_R \mathcal{H}$, $s \in_R S$. Output $(h, s)$.

By the above argument and the Leftover Hash Lemma, it suffices to show that conditioned on any value $\bar{z}$ for $\tilde{C}'(\tilde{b},\tilde{r})$, no triple $(\tilde{b},\tilde{r},\tilde{y})$ has probability more than $2^{-\Omega(n)}/|S|$. The pair $(\tilde{b},\tilde{r})$ comes uniformly from a set of size $2^{w^+}(\bar{z}) \geq 2^{w+\Delta}$, and $\tilde{y}$ is selected independently according to $\tilde{C}'$, so the probability of any triple $(\tilde{b},\tilde{r},\tilde{y})$ is at most
\[ \left( \frac{1}{2^{w-\Delta}} \right) \left( \frac{2^{w+\Delta}}{|T|} \right) \leq \frac{2^{2\Delta}}{(1 - 2^{-\Omega(n)})(2(q+1)m)} = 2^{-\Omega(n)}. \]

Thus, $\|D'_0 - D'_1\| \leq 2^{-\Omega(n)}$, and the claim is established.

Now we treat the other case, when $C_0$ and $C_1$ are statistically close.

**Claim 4.22** If $\|\tilde{C}_0 - \tilde{C}_1\| < 2^{-n}$, then $\|D'_0 - D'_1\| > 1 - 2^{-\Omega(n)}$.

**Proof of claim:** First, we formalize the idea that $\tilde{b}$ is almost completely “undetermined” by $\tilde{C}(\tilde{b},\tilde{r})$. Since $\|\tilde{C}_0 - \tilde{C}_1\| < 2^{-n}$, it follows from Fact 2.6 that with probability $1 - 2^{-\Omega(n)}$ over $z \leftarrow \tilde{C}_0$,
\[ (1 - 2^{-\Omega(n)}) \Pr[\tilde{C}_1 = z] \leq \Pr[\tilde{C}_0 = z] \leq (1 + 2^{-\Omega(n)}) \Pr[\tilde{C}_1 = z]. \]
In other words,
\[
1 - 2^{-\Omega(n)} \leq \frac{|\{ r : \overline{C}_0(r) = z \}|}{|\{ r : \overline{C}_1(r) = z \}|} \leq 1 + 2^{-\Omega(n)}.
\]

The same is true with probability \(1 - 2^{-\Omega(n)}\) when the roles of \(\overline{C}_0\) and \(\overline{C}_1\) are reversed. Thus, with probability \(1 - m2^{-\Omega(n)} = 1 - 2^{-\Omega(n)}\) over \(\vec{z} \leftarrow \overline{C}\), we have for every pair \(\vec{b}, \vec{c} \in \{0,1\}^m\),
\[
1 - 2^{-\Omega(n)} = (1 - 2^{\Omega(n)})^m \leq \frac{|\{ \vec{r} : \overline{C}(\vec{b}, \vec{r}) = \vec{z} \}|}{|\{ \vec{r} : \overline{C}(\vec{c}, \vec{r}) = \vec{z} \}|} \leq (1 + 2^{-\Omega(n)})^m = 1 + 2^{-\Omega(n)}.
\]

Since there are \(2^m\) choices for \(\vec{c}\), this, combined with Lemma 4.19, implies that, with probability \(1 - 2^{-\Omega(n)}\) over \(\vec{z} \leftarrow \overline{C}\), the following holds for every \(\vec{b} \in \{0,1\}^m\):
\[
|\{ \vec{r} : \overline{C}(\vec{b}, \vec{r}) = \vec{z} \}| \leq (1 + 2^{-\Omega(n)}) \cdot \frac{2^{\text{wit}(\vec{z})}}{2^m} \leq (1 + 2^{-\Omega(n)}) \cdot 2^{w+\Delta-m}.
\]

Since this is true with probability \(1 - 2^{-\Omega(n)}\) for \(\vec{z}\) selected according to \(\overline{C}\), it is also true with probability \(1 - 2^{-\Omega(n)}\) for \(\vec{z}\) selected according to \(\overline{C}'\). Fix any such \(\vec{z}\) and fix any \(\vec{b} \in \{0,1\}^m\) and \(h \in \mathcal{H}\). Then, in \(D'_0\), conditioned on \(\overline{C}'(\vec{b}, \vec{r}) = \vec{z}, \vec{b}, \text{ and } h\), there are at most
\[
(1 + 2^{-\Omega(n)}) \cdot 2^{w+\Delta-m} \left( \frac{|\mathcal{T}|}{2^{w+\Delta}} \right) \leq (1 + 2^{-\Omega(n)}) \cdot 2^{2\Delta-m} \cdot 2^{m(q+1)} = (1 + 2^{-\Omega(n)}) \cdot 2^{4\Delta+n-m} \cdot |S| = 2^{-\Omega(n)} \cdot |S|
\]
possible values for \((\vec{r}, \vec{y})\). Thus, with probability at least \(1 - 2^{-\Omega(n)}\), conditioned on values for the first three components of \(D'_0\), the fourth component \(h(\vec{b}, \vec{r}, \vec{y})\) can cover at most a \(2^{-\Omega(m)} \leq 2^{-\Omega(n)}\) fraction of \(S\). In contrast, conditioned on values for the first three components of \(D'_1\), the fourth component is uniformly distributed on \(S\). Therefore, \(\| D'_0 - D'_1 \| \geq 1 - 2^{-\Omega(n)}\).

In [Vad99], it is shown that this Reversal Mapping can be better understood as a composition of two reductions, going the two directions between Statistical Difference and Entropy Difference (the complete problem for SZK given in [GV99], which trivially reduces to its complement).

5 Other Forms of Zero Knowledge

5.1 Weak-SZK and expected polynomial-time simulators

Recall that, in this paper, we defined statistical zero-knowledge with respect to strict polynomial-time simulators. As noted in Section 2, the original definition of statistical zero-knowledge permits expected polynomial-time simulators, but only allowing strict polynomial-time simulators is not very restrictive when discussing honest-verifier proofs, as we are.

However, our techniques do say something about expected polynomial-time simulators, and in particular show that expected polynomial-time simulators are no more powerful than strict ones
for public-coin statistical zero-knowledge. This is the first general equivalence between strict and expected polynomial-time simulators for statistical zero knowledge that we know of.

Indeed, we are able to generalize further to an even weaker notion, that of weak statistical zero knowledge (as previously considered in [DOY97], where it was referred to as “non-uniform simulation”):

**Definition 5.1** An interactive proof system \((P, V)\) for a promise problem \(\Pi\) is weak statistical zero knowledge if for all polynomials \(p\), there exists an efficient probabilistic (strict) polynomial-time algorithm \(S_p\) such that

\[
\|S_p(x) - (P, V)(x)\| \leq 1/p(|x|),
\]

for all sufficiently long \(x \in \Pi_Y\).

We denote by \(\text{weak-SZK}\) the class of promise problems admitting weak statistical zero-knowledge proofs, and by public-coin weak-SZK the class corresponding to such proofs which are also public coin. Note that any proof system admitting an expected polynomial-time simulator (in the usual sense) certainly also satisfies the requirements of weak statistical zero-knowledge. We show that in fact any public-coin weak statistical zero-knowledge proof system can be transformed into a statistical zero-knowledge proof system with a strict polynomial-time simulator achieving negligible (in fact, exponentially small) simulator deviation. In other words, public-coin weak-SZK = SZK.

**Proposition 5.2** public-coin weak-SZK = SZK = public-coin SZK.

The only obstacle in generalizing Proposition 5.2 to all weak statistical zero-knowledge proofs (instead of just public-coin ones) is that Okamoto’s private to public-coin transformation in [Oka00] is only given for strict polynomial-time simulators achieving negligible simulator deviation. In fact, this generalization was accomplished in work (subsequent to ours) by Goldreich and Vadhan [GV99].

In order to establish Proposition 5.2, it suffices to show that every problem in public-coin weak-SZK reduces to SD, as the proposition follows by closure under reductions (Corollary 4.3) and Okamoto’s theorem that \(\text{SZK} = \text{public-coin SZK}\) (Theorem 3.10). Therefore, we need only establish the following generalization of Lemma 3.8:

**Lemma 5.3** Suppose promise problem \(\Pi\) has a public-coin weak statistical zero-knowledge proof. Then there exist probabilistic (strict) polynomial time machines \(A\) and \(B\) such that

\[
x \in \Pi_Y \quad \Rightarrow \quad \|A(x) - B(x)\| < \frac{1}{3}, \text{ and}
\]

\[
x \in \Pi_N \quad \Rightarrow \quad \|A(x) - B(x)\| > \frac{2}{3}.
\]

**Proof:** The proof is identical to the proof of Lemma 3.8, except that wherever the simulator \(S\) is used in that proof, we replace it with \(S_p\), a simulator with deviation \(1/p(n)\), where \(p(n) = 7n \cdot r(n)^3\). Then we replace Claim 3.12 with the following:

**Claim 5.4** If \(x \in \Pi_Y\), then \(\|A(x) - B(x)\| \leq 1/(3|x| \cdot r(|x|)^2)\).

**Proof of claim:** The proof is identical to the proof of Claim 3.12, except that now we have

\[
\|A(x) - B(x)\| \leq 2^{-\Omega(|x|)} + 2r(|x|) \cdot \|S_p(x) - (P, V)(x)\| < \frac{1}{3|x| \cdot r(|x|)^2}.
\]
On the other hand, Claim 3.13 remains true, i.e. \( x \in \Pi_N \) implies \( \|A(x) - B(x)\| \geq 1/12r(n) \). Then, as in the original proof, we consider the samplable distributions \( \tilde{A}(x) = \otimes^s(|x|) A(x) \) and \( \tilde{B}(x) = \otimes^{s(|x|)} B(x) \), where \( s(n) = n \cdot r(n)^2 \). If \( x \in \Pi_Y \), \( \| \tilde{A}(x) - \tilde{B}(x) \| \leq s(|x|) \| A(x) - B(x) \| < 1/3 \), as desired. If \( x \in \Pi_N \), then by the Direct Product Lemma (Lemma 3.4), \( \| A(x) - B(x) \| \geq 1 - 2^{-\Omega(|x|)} \).  

5.2 Perfect and computational zero knowledge

Although the focus of this paper is statistical zero knowledge, some of the techniques also apply to perfect and computational zero knowledge. In particular, for public-coin proof systems we obtain variants of Lemma 3.8 for both perfect and computational zero knowledge. In addition, a restricted version of STATISTICAL DIFFERENCE can be shown to have perfect zero-knowledge proof.

First, we define some variants of SD. For any two constants \( \alpha \) and \( \beta \) with \( \alpha > \beta \), define:

\[
\text{SD}_\alpha^\beta = \{(C_0, C_1) : \|C_0 - C_1\| \geq \alpha \}
\]

\[
\text{SD}_\alpha^\beta = \{(C_0, C_1) : \|C_0 - C_1\| \leq \beta \}
\]

\( \text{SD}^\alpha_\beta \) is irreducible with SD and hence complete for \( \mathsf{SZK} \) whenever \( 1 > \alpha^2 > \beta > 0 \), because the Polarization Lemma generalizes to such thresholds. (See discussion at the end of Section 3.2).

We can almost show that every problem which has a public-coin perfect zero-knowledge proof reduces to \( \text{SD}^{1/2,0}_{1/2} \). The caveats are that either the original proof system must have perfect completeness, or we obtain distributions that are samplable in expected polynomial time rather than circuits.

**Proposition 5.5** Every promise problem having a public-coin perfect zero-knowledge proof with perfect completeness reduces to \( \text{SD}^{1/2,0}_{1/2} \).

**Proof:** It suffices to show that the distributions \( A(x) \) and \( B(x) \) constructed in the proof of Lemma 3.8 have statistical difference 0 on \( \text{YES} \) instances, when the original proof system has perfect completeness and the simulator deviation is 0. Indeed, for \( i \geq 1 \), the distributions \( A_i(x) \) and \( B_i(x) \) are identical if the simulator deviation is 0, and the distributions \( A_0(x) \) and \( B_0(x) \) are identical under the additional assumption that the proof system has perfect completeness.  

We remark that Proposition 5.5 holds more generally for problems possessing public-coin perfect zero-knowledge proof systems for which the probability that \( (P,V)(x) \) accepts can be computed in polynomial time for \( \text{YES} \) instances \( x \). This is the case since \( B_0 \) in the proof above can be changed to output 1 with the appropriate probability.

**Proposition 5.6** Suppose promise problem \( \Pi \) has a public-coin perfect zero-knowledge proof. Then there exist probabilistic expected polynomial time machines \( A \) and \( B \) such that

\[
\begin{align*}
\text{if } x &\in \Pi_Y \Rightarrow \| A(x) - B(x) \| = 0, \text{ and} \\
\text{if } x &\in \Pi_N \Rightarrow \| A(x) - B(x) \| \geq 1 - 2^{-\Omega(|x|)}.
\end{align*}
\]

**Proof:** The proof is nearly identical to that of Proposition 5.5, except that we must modify \( A_0(x) \) and \( B_0(x) \) to have statistical difference 0 (at the price of \( B_0(x) \) becoming expected polynomial time). Let \( c(n) \) be a polynomial bound on the number of random coins \( S \) uses on inputs of length \( n \). Then we define \( A_0 \) and \( B_0 \) as follows (in both descriptions, \( n = |x| \)): 

36
$A_0(x)$: Run $S(x)$ for $n \cdot c(n)$ repetitions. Output ‘1’ if the majority are accepting conversations and ‘0’ otherwise.

$B_0(x)$: With probability $1 - 2^{-c(n)}$, output ‘1’. Otherwise, calculate the probability $\sigma$ that $S(x)$ outputs an accepting conversation (by exhaustive search over all $2^{c(n)}$ random seeds). Now calculate

$$\tau = \sum_{i=0}^{\left\lfloor \frac{nc(n)}{2} \right\rfloor} \binom{nc(n)}{i} \sigma^i (1 - \sigma)^{nc(n) - i}.$$ 

If $\tau > 2^{-c(n)}$, output ‘1’. Otherwise, output ‘0’ with probability $\tau/2^{-c(n)}$, and ‘1’ otherwise.

Note that $B_0(x)$ runs in expected polynomial time, since with probability $2^{-c(n)}$ it runs in time $\text{poly}(n) \cdot 2^{c(n)}$ and otherwise it runs in time $\text{poly}(n)$. Also observe that $\tau$ is exactly the probability that $A_0(x)$ outputs ‘0’.

Now we argue that, when $x \in \Pi_Y$, $A_0(x)$ and $B_0(x)$ have statistical difference 0, i.e. output ‘1’ with the same probability. Since $S(x)$ outputs a conversation which makes $V$ accept with probability at least $2/3 - \text{neg}(n)$, the Chernoff bound implies that $\Pr[A_0(x) = 1] = 1 - 2^{-\Omega(nc(n))}$. This means that $\tau$ will always be less than $2^{-c(n)}$ (for sufficiently large $n$), so $B_0$ will output ‘0’ with probability $2^{-c(n)} \cdot (\tau/2^{-c(n)}) = \tau$, which is the probability that $A_0$ outputs ‘0’.

Now, if we could show that $\text{SD}^{1/2,0}$ (or its complement) has a perfect zero-knowledge proof system, we would have something like a completeness result for $\text{PZK}$. Although we do not know how to do this, we can instead show that $\text{SD}^{1,1/2} \in \text{PZK}$. Indeed, consider the protocol of Section 3.3 with the modification that the two parties use the XOR Lemma (Lemma 3.5) instead of the Polarization Lemma. Then the proof of Lemma 3.7 tells us that this protocol, when used for $\text{SD}^{1,1/2}$, has completeness error 0, simulator deviation 0, and soundness error $1/2 + 2^{-n}$. Thus we have:

**Proposition 5.7** $\text{SD}^{1,1/2} \in \text{PZK}$.

For computational zero knowledge, the techniques of Lemma 3.8 give us something significantly weaker:

**Proposition 5.8** Suppose promise problem $\Pi$ has a public-coin computational zero-knowledge proof. Then there exist probabilistic polynomial time machines $A$ and $B$ such that

1. $x \in \Pi_N \Rightarrow \| A(x) - B(x) \| \geq 1 - 2^{-\Theta(|x|)}$, and

2. $\{ A(x) \}_{x \in \Pi_x}$, and $\{ B(x) \}_{x \in \Pi_y}$ are computationally indistinguishable ensembles of probability distributions.

Note that, in contrast to perfect and statistical zero knowledge, the conditions given in Proposition 5.8 do not give a way to distinguish YES and NO instances; it is possible for $A(x)$ and $B(x)$ to have statistical difference greater than $1 - 2^{-\Omega(|x|)}$ even for $x \in \Pi_Y$. Despite this, it still suffices to establish Theorem 5.13, which we present in Section 5.3. We also remark that Proposition 5.8 holds even when the simulator for the proof system runs in expected polynomial time, except that $A$ and $B$ will also run in expected polynomial time.
Proof: The proof follows Lemma 3.8 exactly, except for Claim 3.12, which should be replaced with the following:

Claim 5.9 \( \{A(x)\}_{x \in \Pi_Y} \) and \( \{B(x)\}_{x \in \Pi_Y} \) are computationally indistinguishable ensembles of probability distributions.

We omit \( x \) from the notation for readability; below all probability distributions actually refer to ensembles indexed by \( x \in \Pi_Y \). The proof in Claim 3.12 that \( A_0 \) and \( B_0 \) have exponentially small statistical difference still holds. Let the distributions \( A' \) and \( B' \) be obtained from \( A \) and \( B \) by removing the 0th component of \( A \) and \( B \), respectively. Since \( A_0 \) and \( B_0 \) are independent of \( A' \) and \( B' \), it suffices to show that \( A' \) and \( B' \) are computationally indistinguishable. To prove this, we first note that a hybrid argument shows that the distributions \( \otimes^r (P,V) \) and \( \otimes^r S \) are computationally indistinguishable, since \( (P,V) \) and \( S \) are computationally indistinguishable. Note that this step uses the fact that our definition of computational indistinguishability is with respect to nonuniform distinguishers, because \( (P,V) \) is not a samplable distribution (cf., [Goldreich, Ch. 3, Exercise 9]).

Now we introduce a new distribution \( C \). Define \( C_i = (c_1, p_1, \ldots, c_r) \) for \( 1 \leq i \leq r \), and let \( C = C_1 \otimes \cdots \otimes C_r \). Then \( C \) and \( A' \) are computationally indistinguishable since a distinguisher \( D \) between them could be used to make \( A' \) a distinguisher \( D' \) between \( \otimes^r (P,V) \) and \( \otimes^r S \): Given a sequence of \( r \) transcripts \( (t_1, \ldots, t_r) \), \( D' \) truncates \( t_i = (c_1, p_1, \ldots, c_r, p_r) \) to produce \( t_i' = (c_1, p_1, \ldots, c_i) \) and feeds \( (t_1', \ldots, t_r') \) to \( D \). When fed with \( \otimes^r S \), \( D' \) gives \( D \) a sample of \( A' \), and when fed with \( \otimes^r (P,V) \), \( D' \) gives \( D \) a sample of \( C \).

Similarly, \( C \) and \( B' \) are also computationally indistinguishable because a distinguisher between them could be used to make \( B' \) a distinguisher \( D' \) between \( \otimes^r (P,V) \) and \( \otimes^r S \): Given a sequence of \( r \) transcripts \( (t_1, \ldots, t_r) \), \( D' \) truncates \( t_i = (c_1, p_1, \ldots, c_r, p_r) \) and selects \( u_i \) according to the uniform distribution on strings of length \( r(\mid x \mid) \) to produce \( t_i' = (c_1, p_1, \ldots, p_{i-1}, u_i) \) and feeds \( (t_1', \ldots, t_r') \) to \( D \). When fed with \( \otimes^r S \), \( D' \) gives \( D \) a sample of \( B' \), and when fed with \( \otimes^r (P,V) \), \( D' \) gives \( D \) a sample of \( C \).

Now, because both \( A' \) and \( B' \) are computationally indistinguishable from \( C \), they must be computationally indistinguishable from each other, completing the proof.

5.3 Hard-on-average problems and one-way functions

Most, if not all, of cryptography relies on the existence of computational problems which are hard-on-average. However, the mere existence of a hard-on-average problem, even in \( \text{NP} \), is not known to imply even the most basic cryptographic primitive, namely a one-way function. Ostrovsky [Ost91], however, showed that the existence of a hard-on-average problem in \( \text{SZK} \) does imply the existence of one-way functions. This result was subsequently generalized to CZK by Ostrovsky and Wigderson [OW93].

In this section, we show how Ostrovsky’s result follows readily from our Completeness Theorem and a result of Goldreich [Goldreich90] on computational indistinguishability. Using the generalization of our techniques to CZK described in the previous section, we also obtain a simpler proof of the Ostrovsky–Wigderson Theorem restricted to public-coin proof systems.

In order to state these theorems precisely, we need to define what we mean for a problem \( \Pi \) to be “hard.” Informally, we require that membership in \( \Pi \) is (very) hard to decide under some samplable distribution of instances.
Definition 5.10 An ensemble of distributions \( \{D_n\}_{n \in \mathbb{N}} \) is said to be samplable if there is a probabilistic polynomial-time algorithm that, on input \( 1^n \) outputs a string distributed according to \( D_n \).

Definition 5.11 A promise problem \( \Pi \) is hard-on-average if there exists a samplable ensemble of distributions \( \{D_n\}_{n \in \mathbb{N}} \) such that the following holds: For every nonuniform probabilistic polynomial-time algorithm \( M \), there exists a negligible function \( \mu : \mathbb{N} \to [0, 1] \) such that

\[
\Pr[M(x) \text{ correctly decides whether } x \text{ is a YES or NO instance of } \Pi] \leq \frac{1}{2} + \mu(n) \quad \forall n \in \mathbb{N},
\]

where the probability is taken over \( x \leftarrow D_n \) and the coins of \( M \). (If \( x \) violates the promise, then \( M \) is considered to be correct no matter what it outputs.)

In this section, we will give new proofs of the following results.

Theorem 5.12 ([Ost91]) If there is a hard-on-average promise problem in SZK, then one-way functions exist.

Theorem 5.13 ([OW93] for public-coin proofs) If a hard-on-average promise problem possesses a public-coin computational zero-knowledge proof system, then one-way functions exist.

We will only prove Theorem 5.13 as Theorem 5.12 then follows via Theorem 3.10 [Oka00]. Our proof will make use of Proposition 5.8 in conjunction with the following result of Goldreich [Gol90]:

Proposition 5.14 ([Gol90]) Suppose there exist two samplable ensembles of distributions, \( \{A_n\}_{n \in \mathbb{N}} \) and \( \{B_n\}_{n \in \mathbb{N}} \), such that

1. \( \{A_n\} \) and \( \{B_n\} \) are computationally indistinguishable.

2. There is a polynomial \( p : \mathbb{N} \to \mathbb{N} \) such that for all \( n \), \( \|A_n - B_n\| \geq 1/p(n) \).

Then one-way functions exist.

Proof of Theorem 5.12: Suppose \( \Pi \) is a hard-on-average problem with a public-coin computational zero-knowledge proof and let \( \{D_n\} \) be the ensemble of distributions under which \( \Pi \) is hard. By Proposition 5.8 there are probabilistic polynomial-time algorithms \( A \) and \( B \) such that

1. \( x \in \Pi_N \Rightarrow \|A(x) - B(x)\| \geq 1 - 2^{-\Omega(|x|)} \), and

2. \( \{A(x)\}_{x \in \Pi_Y} \) and \( \{B(x)\}_{x \in \Pi_Y} \) are computationally indistinguishable.

(Note that if \( \Pi \in \text{SZK} \), the Completeness Theorem and Polarization Lemma yield such \( A \) and \( B \) with the computational indistinguishability replaced by statistical difference \( 2^{-|x|} \).)

We will show that the following ensembles \( \{A_n\} \) and \( \{B_n\} \) meet the requirements of Proposition 5.14:

\( A_n \): Sample \( x \) according to \( D_n \). Sample \( z \) from \( A(x) \). Output \( (x, z) \).

\( B_n \): Sample \( x \) according to \( D_n \). Sample \( z \) from \( B(x) \). Output \( (x, z) \).
The statistical farness of these ensembles will follow from the farness of $A(x)$ and $B(x)$ on NO instances. The computational indistinguishability will follow from the computational indistinguishability of $A(x)$ and $B(x)$ on YES instances, together with the fact that it is hard to distinguish YES instances of $\Pi$ from NO instances.

To formalize this intuition, we make some observations which follow from the fact that $\Pi$ is hard-on-average (where here and throughout this proof, we write $\text{neg}(n)$ to denote negligible functions):

1. $\Pr[D_n \notin \Pi_Y \cup \Pi_N] = \text{neg}(n)$.
2. $|\Pr[D_n \in \Pi_Y] - \frac{1}{2}| = \text{neg}(n)$ and $|\Pr[D_n \in \Pi_Y] - \frac{1}{2}| = \text{neg}(n)$.
3. The ensembles $\{D_n^Y\}_{n \in \mathbb{N}}$ and $\{D_n^N\}_{n \in \mathbb{N}}$ obtained by conditioning $D_n$ on being a YES or NO instance, respectively, are computationally indistinguishable.

Items 1 and 2 hold because otherwise the trivial algorithm that always outputs YES or the one that always outputs NO would decide $\Pi$ correctly with nonnegligible advantage. Item 3 holds because a distinguisher between $\{D_n^Y\}$ and $\{D_n^N\}$ could be used to decide $\Pi$ with nonnegligible advantage.

**Claim 5.15** $\|A_n - B_n\| \geq 1/2 - \text{neg}(n)$.

**Proof of claim:** Since $D_n$ must produce a NO instance of $\Pi$ with probability at least $1/2 - \text{neg}(n)$, $\|A_n - B_n\| \geq (1/2 - \text{neg}(n)) \cdot (1 - 2^{-\Omega(n)}) = 1/2 - \text{neg}(n)$.

**Claim 5.16** $\{A_n\}_{n \in \mathbb{N}}$ and $\{B_n\}_{n \in \mathbb{N}}$ are computationally indistinguishable.

**Proof of claim:** Let $M$ be any probabilistic polynomial-time algorithm. From the fact that $A(x)$ and $B(x)$ are computationally indistinguishable for YES instances, it follows that

$$|\Pr[M(x, A(x)) = 1|x \in \Pi_Y] - \Pr[M(x, B(x)) = 1|x \in \Pi_Y]| = \text{neg}(n),$$

where these probabilities (and all those to follow) are taken over $x \leftarrow D_n$ and the coins of all algorithms ($M$, $A$, and $B$). By the computational indistinguishability of $\{D_n^Y\}$ and $\{D_n^N\}$, we also have

$$|\Pr[M(x, A(x)) = 1|x \in \Pi_Y] - \Pr[M(x, A(x)) = 1|x \in \Pi_N]| = \text{neg}(n)$$

and

$$|\Pr[M(x, B(x)) = 1|x \in \Pi_Y] - \Pr[M(x, B(x)) = 1|x \in \Pi_N]| = \text{neg}(n).$$

Combining these with Equation 3, we see that all four conditional probabilities differ only by negligible amounts. Therefore,

$$\Pr[M(x, A(x)) = 1] - \Pr[M(x, B(x)) = 1]$$

$$\leq |\Pr[M(x, A(x)) = 1|x \in \Pi_Y] - \Pr[M(x, B(x)) = 1|x \in \Pi_Y]|$$

$$+ |\Pr[M(x, A(x)) = 1|x \in \Pi_N] - \Pr[M(x, B(x)) = 1|x \in \Pi_N]|$$

$$+ 2\Pr[x \notin \Pi_Y \cup \Pi_N]$$

$$= \text{neg}(n).$$

This establishes the computational indistinguishability of $\{A_n\}$ and $\{B_n\}$.

Given these claims, the result now follows from Proposition 5.14.
5.4 Extensions to cheating-verifier zero knowledge

The focus of study in this paper has been the class of languages (or promise problems) possessing statistical zero-knowledge proofs against an honest verifier. However, in cryptographic applications, one usually wants the zero-knowledge condition to hold even against cheating verifier strategies that deviate arbitrarily from the specified protocol. There have been a number of results showing how to transform proof systems which are statistical zero knowledge against the honest-verifier into ones that are statistical zero knowledge against cheating verifier strategies [BMO90, OVY93, Dam93, DGOW95, Oka00, GSV98]. As advocated in [BMO90], one can use such transformations to translate results like ours about honest-verifier statistical zero knowledge to the cheating-verifier definition. In this section, we discuss which of our results apply to the cheating-verifier class and the appropriate formulations in each case.

**Definition 5.17** An interactive protocol between a computationally unbounded prover $P$ and a PPT verifier $V$ is said to be a cheating-verifier statistical zero-knowledge proof system for a promise problem $\Pi$ if the following holds:

1. If $x \in \Pi_Y$, then $\Pr[(P, V)(x) = \text{accept}] \geq 1 - c(|x|)$.

2. If $x \in \Pi_N$, then for all $P^*$, $\Pr[(P^*, V)(x) = \text{accept}] \leq s(|x|)$.

3. For all PPT $V^*$, there exists a PPT $S$ and negligible function $\alpha(\cdot)$ such that for all $x \in \Pi_Y$, $\| S(x) - \text{View}_{P,V^*}(x) \| \leq \alpha(|x|)$.

As usual, $c(\cdot)$ is called the completeness error, $s(\cdot)$ the soundness error, and $\alpha(\cdot)$ the simulator deviation for $V^*$. cheating-ver SZK denotes the class of promise problems possessing cheating-verifier statistical zero-knowledge proofs.

Bellare, Micali, and Ostrovsky [BMO90] gave the first evidence that cheating-ver SZK = SZK, by proving it under the DISCRETE LOGARITHM assumption. Following sequence of subsequent works [OVY93, Dam93, DGOW95], the complexity assumption was recently completely removed:

**Theorem 5.18** ([Oka00, GSV98]) cheating-ver SZK = SZK. Moreover, there is a transformation which converts an honest-verifier statistical zero-knowledge proof $(P, V)$ for a promise problem $\Pi$ into cheating-verifier statistical zero-knowledge proof $(P', V')$ for $\Pi$ such that:

- $(P', V')$ is public coin.
- $(P', V')$ has perfect completeness and soundness error $2^{-n}$.
- $(P', V')$ has a universal black-box simulator $S$ which works for all (even computationally unbounded) verifier strategies $V^*$.
- If $(P, V)$ has simulator deviation $\alpha(n)$, then $(P', V')$ has simulator deviation $\text{poly}(n) \cdot \alpha(n) + 2^{-n}$ for every $V^*$.
- If $(P, V)$ is security-parameterized, then so is $(P', V')$.

We now use this result to translate our results about honest-verifier statistical zero knowledge to cheating-verifier statistical zero knowledge.

---

14See [GSV98] for a definition.

15This is not stated explicitly in [Oka00, GSV98], but can be achieved replacing the input length $n$ with $\max\{k, n\}$, where $k$ is the security parameter, in their constructions.
Class Properties. Since Theorem 5.18 asserts an equality of classes, all of our results about the class $SZK$ also hold for cheating-ver $SZK$:

Corollary 5.19 (properties of the class cheating-ver $SZK$)

- **Statistical Difference is complete for** cheating-ver $SZK$.
- **cheating-ver $SZK$ is closed under Karp reductions, complement [Oka00], $\Phi(\cdot)$, and NC$^1$ truth-table reductions.**
- **If there is a hard-on-average problem in cheating-ver $SZK$, then one-way functions exist [Ost91].**

Proof: Combine Theorem 5.18 with Theorem 3.1, Corollary 4.3, Corollary 4.4, Theorem 4.9, Corollary 4.14, and Theorem 5.12.

Protocol Properties. Unfortunately, Theorem 5.18 does not guarantee that every property satisfied by the honest-verifier proof system $(P, V)$ is also satisfied by the cheating-verifier proof system $(P', V')$. Thus, although we have shown in Corollary 4.2 that every problem in $SZK$ has a very efficient honest-verifier proof, it does not follow that it also has a cheating-verifier proof of similar efficiency. In particular, Theorem 5.18 does not preserve (even up to constant factors) the message complexity, communication complexity, or deterministic prover of Corollary 4.2.\footnote{In fact it is necessary that some of these properties are not maintained: only problems in $BPP$ have cheating-verifier statistical zero-knowledge proofs with deterministic provers [GO94], and only problems in $BPP$ have cheating-verifier statistical zero-knowledge proofs which are constant round, public coin and have universal black-box simulators [GK96].}

The only aspects of Corollary 4.2 that are maintained involve the error probabilities:

Corollary 5.20 Every problem in $SZK$ has a security-parameterized cheating-verifier statistical zero-knowledge proof with perfect completeness, soundness error $2^{-k}$, and simulator deviation $2^{-k}$.

Proof: Apply Theorem 5.18 to Corollary 4.2.

We note that the transformation of Bellare, Micali, and Ostrovsky [BMO90] does preserve the message complexity of the proof system up to a constant factor, but requires the assumption that the Discrete Logarithm problem is hard. Thus, under this assumption, their transformation can be combined with Okamoto’s result that every problem in $SZK$ has a constant-message honest-verifier proof system [Oka00] (or Corollary 4.2) and conclude that every problem in $SZK$ has a constant-message cheating-verifier proof system.

Knowledge complexity. Since Theorem 5.18 only refers to statistical zero-knowledge, we cannot immediately apply it our results about (non-zero) knowledge complexity. Below, we show how this nevertheless can be done for our results about knowledge complexity in the hint sense.

First, for all the variants of knowledge complexity discussed in Section 4.3, we can define cheating-verifier knowledge complexity analogously to Definition 5.17. We denote the cheating-verifier variant of a class $C$ with cheating-ver $C$. We begin by showing that honest-verifier and cheating-verifier statistical knowledge complexity in the hint sense coincide. To prove this, we observe one direction of the characterization of knowledge complexity in the hint sense given by Lemma 4.16 also holds for the cheating-verifier classes:
Lemma 5.21 Let \( \Pi \) be any promise problem and let \( k(n) \) be any polynomially bounded function. Suppose there exists a promise problem \( \Gamma \in \text{cheating-ver} \text{ SZK} \) (resp., cheating-ver \text{ PZK}) such that

1. \( x \in \Pi_Y \Rightarrow \text{there exists a such that } |a| = k(|x|) \) and \( (x, a) \in \Gamma_Y \), and
2. \( x \in \Pi_N \Rightarrow \text{for all } a, (x, a) \in \Gamma_N \).

Then \( \Pi \in \text{cheating-ver} \text{ SKC}_{\text{hint}}(k(n)) \) (resp., cheating-ver \text{ PKC}_{\text{hint}}(k(n)))

The proof of Lemma 5.21 is the same as the corresponding direction of Lemma 4.16. The reason the other direction of Lemma 4.16 does not immediately apply to the cheating-verifier case is that the hint function may be different for each verifier. However, we can deduce that direction from the following:

**Proposition 5.22** For every polynomially-bounded function \( k(n) \),

\[
\text{SKC}_{\text{hint}}(k(n)) = \text{cheating-ver} \text{ SKC}_{\text{hint}}(k(n)).
\]

**Proof:** Clearly, cheating-ver \text{ SKC}_{\text{hint}}(k(n)) \subset \text{SKC}_{\text{hint}}(k(n)). Now suppose \( \Pi \) is any language in \text{SKC}_{\text{hint}}(k(n)), and let \( \Gamma \in \text{SZK} \) be the promise problem guaranteed by Lemma 4.16. Then, by Theorem 5.18, \( \Gamma \in \text{cheating-ver} \text{ SZK} \). Applying Lemma 5.21, we see that \( \Pi \in \text{cheating-ver} \text{ SKC}_{\text{hint}}(k(n)) \).

Observe that we have actually proved something stronger: if \( \Pi \in \text{SKC}_{\text{hint}}(k(n)) \), then there is a proof system for \( \Pi \) with cheating-verifier statistical knowledge complexity \( k(n) \) for which the *same hint function* can be used for every verifier. Unfortunately, analogues of Proposition 5.22 do not appear to follow immediately from the fact that \( \text{SZK} = \text{cheating-ver} \text{ SZK} \).

Given Proposition 5.22, it follows immediately that the collapse in the \text{SKC}_{\text{hint}} hierarchy (Theorem 4.15) also holds for the cheating-verifier classes:

**Proposition 5.23** For any polynomially bounded function \( k(n) \),

\[
\text{cheating-ver} \text{ SKC}_{\text{hint}}(k(n) + \log n) = \text{cheating-ver} \text{ SKC}_{\text{hint}}(k(n)).
\]

In contrast, we do not know whether our results on the perfect knowledge complexity of \( \text{SZK} \) hold for the analogous cheating-verifier classes. To apply the same approach, one would have to analyze the (cheating-verifier) perfect knowledge complexity of the protocols obtained by performing the transformations of [Oka00] and [GSV98] on the protocol for SD. These transformations could conceivably increase the perfect knowledge complexity dramatically.

## 6 Open Problems

We recall some of the open problems we mentioned throughout the paper, along with some additional research problems raised by this work.

- **Does Statistical Difference remain complete for \( \text{SZK} \) and the Polarization Lemma (Lemma 3.3) still hold when the thresholds are \( \alpha, \beta \) such that \( \alpha^2 < \beta < \alpha \)?**

- **Is \( \text{SZK} \) closed under general Cook reductions (adaptive or nonadaptive)?** (Recall that in Corollary 4.14, we showed that \( \text{SZK} \) is closed under \( \text{NC}_1 \) truth-table reductions.)
• Do the other forms of statistical knowledge complexity collapse like the $\text{SK}_{\text{hint}}$ hierarchy (cf., Theorem 4.15)?

• Find natural complete problems for $\text{PZK}$ or $\text{CZK}$. (The results of Section 5.2 are efforts in this direction.)

• Find additional natural complete problems for $\text{SZK}$, e.g. combinatorial or number-theoretic problems. While we have used $\text{SZK}$-completeness mainly as a positive tool, it could also provide strong evidence of intractability, as $\text{SZK}$ contains many problems believed to be hard.

• Does $\text{SZK} = \text{PZK}$? It was this question, posed to us by Shafi Goldwasser, that started us on this research, and unfortunately the answer remains a mystery. However, our Completeness Theorem does imply that $\text{SZK} = \text{PZK}$ if and only if Statistical Difference is in $\text{PZK}$.

Acknowledgements

We are grateful to our advisor, Shafi Goldwasser, for getting us started on the topic of statistical zero knowledge and providing direction and advice throughout our work. We are indebted to Oded Goldreich for many enlightening conversations and subsequent collaboration on this topic, and his extensive help with the writing of this paper. We also thank Mihir Bellare, Erez Petrank, Tatsuaki Okamoto, Madhu Sudan, Luca Trevisan, Avi Wigderson, and the anonymous conference and journal reviewers for many helpful suggestions, clarifying discussions, and/or encouragement.

A The Statistical Difference Metric

Proof of Fact 2.1: For any set $S \subseteq D$,
\[
2|\Pr[X \in S] - \Pr[Y \in S]| = |\Pr[X \in S] - \Pr[Y \in S] + \Pr[X \not\in S] - \Pr[Y \not\in S]| \\
= \left| \sum_{x \in S} (\Pr[X = x] - \Pr[Y = x]) \right| + \left| \sum_{x \not\in S} (\Pr[X = x] - \Pr[Y = x]) \right| \\
\leq \sum_{x \in S} |\Pr[X = x] - \Pr[Y = x]| + \sum_{x \not\in S} |\Pr[X = x] - \Pr[Y = x]| \\
= |X - Y|_1.
\]
Equality is achieved by taking $S = \{x : \Pr[X = x] > \Pr[Y = x]\}$.  \[ \blacksquare \]

Proof of Fact 2.3:
\[
\| (X_1, X_2) - (Y_1, Y_2) \| \leq \| (X_1, X_2) - (Y_1, X_2) \| + \| (Y_1, X_2) - (Y_1, Y_2) \| \\
= \frac{1}{2} \| X_1 \otimes X_2 - Y_1 \otimes X_2 \| + \frac{1}{2} \| Y_1 \otimes X_2 - Y_1 \otimes Y_2 \| \\
= \frac{1}{2} \| (X_1 - Y_1) \otimes X_2 \| + \frac{1}{2} \| Y_1 \otimes (X_2 - Y_2) \| \\
= \frac{1}{2} \| X_1 - Y_1 \| \| X_2 \| + \frac{1}{2} \| Y_1 \| \| X_2 - Y_2 \| \\
= \| X_1 - Y_1 \| + \| X_2 - Y_2 \|.
\]
\[ \blacksquare \]

Proof of Fact 2.4: Let $A = (f, R)$ be any randomized procedure. Then, for any set $S \subseteq F$,
\[
|\Pr[A(X) \in S] - \Pr[A(Y) \in S]| = |\Pr[f(X \otimes R) \in S] - \Pr[f(Y \otimes R) \in S]| \\
= |\Pr[X \otimes R \in f^{-1}(S)] - \Pr[Y \otimes R \in f^{-1}(S)]| \\
\leq \| X \otimes R - Y \otimes R \| \\
\leq \| X - Y \| + \| R - R \| \quad \text{(by Fact 2.3)} \\
= \| X - Y \|. \\
\]
Taking the maximum over all sets $S$ completes the proof.  \[ \blacksquare \]

Proof of Fact 2.5: Let $T \subseteq D$ be the set of $x$'s for which $\| X_2 |_{X_1=x} - Y_2|_{Y_1=x} \| < \delta$. Now, let $S$ be an arbitrary subset of $D \times E$ and, for every $x \in D$, define $S_x = \{y \in E : (x, y) \in S\}$. Then,
\[
\Pr[X \in S] \leq \Pr[X_1 \not\in T] + \sum_{x \in T} \Pr[X_2 \in S_x | X_1 = x] \cdot \Pr[X_1 = x] \\
< \epsilon + \sum_{x \in T} (\Pr[Y_2 \in S_x | Y_1 = x] + \delta) \cdot \Pr[Y_1 = x] \\
\leq \epsilon + \delta + \Pr[Y \in S].
\]
By symmetry, we also have $\Pr[Y \in S] < \epsilon + \delta + \Pr[X \in S]$. Since $S$ was arbitrary, $\| X - Y \| < \epsilon + \delta$.  \[ \blacksquare \]
Proof of Fact 2.6: Let \( S = \{ x : (1 - \sqrt{\varepsilon}) \Pr[X = x] \geq \Pr[Y = x] \} \), i.e. the set of \( x \)'s for which the left-hand inequality in Fact 2.6 is violated. Then,

\[
\Pr[Y \in S] \leq (1 - \sqrt{\varepsilon}) \Pr[X \in S] = \Pr[X \in S] - \sqrt{\varepsilon} \cdot \Pr[X \in S].
\]

Thus, \( \sqrt{\varepsilon} \cdot \Pr[X \in S] \leq \|X - Y\| < \varepsilon \), so we must have \( \Pr[X \in S] < \sqrt{\varepsilon} \). A similar argument shows that the right-hand inequality in Fact 2.6 is violated with probability less than \( \sqrt{\varepsilon} \). □

B A Generic Complete Problem for PZK

In this section, we show how to obtain a complete promise problem for PZK directly from the definition of the class. However, in contrast to Statistical Difference, this problem will be essentially a restatement of the definition of the class and therefore of little use.

The complete promise problem for PZK is PZK-Generic, which we now define. An instance of PZK-Generic is a quadruple \((V, S, x, 1^t)\), where \( V \) is a description of an interactive probabilistic Turing machine and \( S \) is a description of a (noninteractive) probabilistic Turing machine. A yes instance is such a quadruple for which there exists a prover strategy \( P \) such that

1. The interaction between \( P \) and \( V \) on \( x \) takes at most \( t \) steps (including the computation time for \( V \)) and \( V \) accepts in this interaction with probably at least \( 2/3 \).

2. The running time of \( S \) on input \( x \) is at most \( t \).

3. \( S \) outputs fail with probability at most \( 1/2 \), and conditioned on not failing, the output distribution of \( S \) is identical to \( V \)'s view of the interaction with \( P \) on \( x \).

A no instance is a quadruple such that for all prover strategies \( P \),

1. The interaction between \( P \) and \( V \) on \( x \) takes at most \( t \) steps (including the computation time for \( V \)) and \( V \) rejects in this interaction with probability at least \( 2/3 \).

2. The running time of \( S \) on input \( x \) is at most \( t \).

Proposition B.1 PZK-Generic is complete for PZK.

Proof: First we show that every promise problem \( \Pi \) in PZK reduces to PZK-Generic. Let \((P, V)\) be the perfect zero-knowledge proof system for \( \Pi \) with simulator \( S \). Let \( t(n) \) be a (polynomial) upper bound on both the running time of \( S \) and the number of steps of the interaction of \( P \) and \( V \) on inputs of length \( n \). Then

\[
x \mapsto (V, S, x, 1^{t(|x|)})
\]

is a polynomial-time reduction from \( \Pi \) to PZK-Generic.

Now we argue that PZK-Generic \( \in \) PZK. Consider the following descriptions of a verifier \( \overline{V} \), a prover \( \overline{P} \), and a simulator \( \overline{S} \):

\[
\overline{V}(V, S, x, 1^t): \text{ When interacting with any machine, simulate } V \text{ on input } x.
\]
\[ \overline{P}(V, S, x, 1^t) \]: Exhaustively search for a prover strategy \( P \) for which \( V \)'s view of \((P, V)(x)\) is identical to the output distribution of \( S(x) \) (conditioned on \( S(x) \neq \text{fail} \)). If one exists, follow that strategy, otherwise output \text{fail}.\(^{17}\)

\[ \overline{S}(V, S, x, 1^t) \]: Simulate \( S \) on input \( x \).

It is easy to see that these definitions provide a perfect zero-knowledge proof system for \( \text{PZK-Generic} \). ■

The problem with extending this example to \( \text{SZK} \) is Condition 3 for \( \text{YES} \) instances. "Identical" needs to be replaced by "negligible statistical difference," but it is not clear what negligible function to put there. We do not know how to get around this difficulty without using our Completeness Theorem, which implies that every problem in \( \text{SZK} \) has a statistical zero-knowledge proof with the same simulator deviation \( 2^{-n} \) (cf., Corollary 4.2).\(^{18}\)

Another observation worth mentioning, pointed out to us by Mihir Bellare, Oded Goldreich, and Madhu Sudan, is that \( \text{PZK-Generic} \) can be modified to obtain complete promise problems for cheating-ver \( \text{PZK} \) (as long as we restrict to "black-box" simulation) and also the various forms of PKC.

C An Example for \textbf{GRAPH ISOMORPHISM}

For illustrative purposes, here we explicitly describe what happens when the reduction to and proof system for \textbf{Statistical Difference} are applied to the well-known public-coin perfect zero-knowledge proof system for \textbf{GRAPH ISOMORPHISM} [GMW91]:

\textbf{Perfect zero-knowledge proof system for GRAPH ISOMORPHISM.}

\textbf{Input:} \((G_0, G_1)\).

1. \( P \) sends \( V \) a random isomorphic copy \( H \) of \( G_0 \).
2. \( V \) picks \( b \in \{0, 1\} \) at random and sends it to \( P \).
3. \( P \) sends \( V \) a random isomorphism \( \pi \) between \( G_b \) and \( H \), if one exists.
4. \( V \) checks that \( \pi G_b = H \).

\textbf{Simulator} \( S \), on input \((G_0, G_1)\):

1. Pick random \( b \in \{0, 1\} \) and a random permutation \( \pi \).
2. Output \((\pi G_b, b, \pi)\).

Notice that the conversations output by \( S \) always make \( V \) accept.

If the reduction to SD from the proof of Lemma 3.8 is applied to the above protocol, the following distributions are obtained:

\(^{17}\)Alternatively, \( \overline{P} \) can act as the \underline{simulation-based prover} (see Section 3.5).

\(^{18}\)We do not know how to overcome this difficulty by using the result of Bellare [Bel97], which states that any \underline{countable} set of negligible functions is "dominated" by a single negligible function. The reason is that there are uncountably many problems in the promise-class \( \text{SZK} \).
$A_0(G_0, G_1)$: Always output 1.
$B_0(G_0, G_1)$: Always output 1.
$A_1(G_0, G_1)$: Output $(\pi G_b, b)$ for a random permutation $\pi$ and $b \in \{0, 1\}$ chosen at random.
$B_1(G_0, G_1)$: Output $(\pi G_b, c)$ for a random permutation $\pi$ and $b$ and $c$ chosen uniformly and independently from $\{0, 1\}$.

Thus, $\|A_0(x) - B_0(x)\|$ always equals 0. $\|A_1(x) - B_1(x)\|$ is easily seen to be 0 if $G_0 \cong G_1$ and 1/2 if $G_0 \not\cong G_1$. For the rest of this section, we ignore $A_0$ and $B_0$ since they are irrelevant.

If we now apply the protocol for SD from Section 3.3 to the distributions $A_1$ and $B_1$ (without first applying the Polarization Lemma), we obtain the following proof system $(P', V')$ for GRAPH NONISOMORPHISM:

1. $V'$ picks a random bit $d \in \{0, 1\}$. If $d = 0$, $V'$ chooses a random bit $b \in \{0, 1\}$ and a random permutation $\pi$ and sends $(\pi G_b, b)$ to $P'$. If $d = 1$, $V'$ chooses random bits $b, c \in \{0, 1\}$ and a random permutation $\pi$ and sends $(\pi G_b, c)$ to $P'$.

2. $P'$ receives message $(H, b)$ from $V'$. $P$ attempts to guess $d$ as follows: If $H$ is isomorphic to $G_b$, then $P'$ guesses 0, else $P'$ guesses 1.

3. $V'$ accepts if the $P'$ guesses $d$ correctly.

Now, if $G_0$ is not isomorphic to $G_1$, then $P'$ will guess correctly with probability 3/4. However, if $G_0$ is isomorphic to $G_1$, then no prover can guess correctly with probability greater than 1/2. The above protocol is of the same spirit as the standard GRAPH NONISOMORPHISM protocol [GMW91]. In both cases, the verifier randomly permutes one of the graphs to obtain a graph $H$ and in order for the prover to succeed with probability greater than 1/2, the prover needs to be able to identify from which graph $H$ came.
