Increasing atmospheric carbon dioxide is responsible for climate changes that are having widespread effects on biological systems. One of the clearest changes is earlier onset of spring and lengthening of the growing season. We designed the present study to examine the interactive effects of timing of dormancy release of seeds with low and high atmospheric CO2 on biomass, reproduction, and phenology in ragweed plants (Ambrosia artemisiifolia L.), which produce highly allergenic pollen. We released ragweed seeds from dormancy at three 15-day intervals and grew plants in climate-controlled glasshouses at either ambient or 700-ppm CO2 concentrations, placing open-top bags over inflorescences to capture pollen. Measurements of plant height and weight, inflorescence number, weight, and length; and days to anthesis and anthesis date were made on each plant, and whole-plant pollen productivity was estimated from an allometric-based model. Timing and CO2 interacted to influence pollen production. At ambient CO2 levels, the earlier cohort acquired a greater biomass, a higher average weight per inflorescence, and a larger number of inflorescences; flowered earlier; and had 54.8% greater pollen production than did the latest cohort. At high CO2 levels, plants showed greater biomass and reproductive effort compared with those in ambient CO2 but only for later cohorts. In the early cohort, pollen production was similar under ambient and high CO2, but in the middle and late cohorts, high CO2 increased pollen production by 32% and 55%, respectively, compared with ambient CO2 levels. Overall, ragweed pollen production can be expected to increase significantly under predicted future climate conditions. Key words: allergenic pollen, Ambrosia artemisiifolia, climate change, climate variability, elevated CO2, global warming, ragweed, springtime warming. for CO₂ fixation during photosynthesis which should thrive in enriched CO₂ atmospheres) common to roadways and disturbed habitats throughout most of the United States and Canada (Bassett and Crompton 1975). It is monocious, with separate male and female flowers borne on the same plant on distinct axillary branches, allowing for independent control of allocation to sexes (Payne 1963).

Seeds of *A. artemisiifolia* collected from wild populations in Woodstock, Illinois, were vernalized by sowing seeds in six growth containers containing compost (Pro-Mix, Red Hill, PA) and storing in a refrigerator at 4°C until ready for germination. Two trays at a time were transferred from cold conditions to the glasshouses at three 15-day intervals, creating three temporal cohorts that would simulate variability in the onset of the growing season and would include anticipated advances of spring several decades into the future. One tray from each cohort was placed in 380 ppm (ambient) and the other at 700 ppm (elevated) CO₂ concentration. From each pair of trays, seedlings were chosen that all germinated on the same day; the germination dates (23 May 2002, 7 June 2002, and 22 June 2002) were also at 15-day intervals. The middle cohort approximates the germination date of plants in the Boston area (Rogers C., personal observation).

Approximately 15 days after their germination, we transplanted 24 seedlings from each tray into 6-dry-quart–capacity growth containers (22.23 cm diameter × 21.59 cm deep). Soil in each container was composed of a 4:1 mix of Pro-Mix compost and washed sand (Quickrete Co., Atlanta, GA). The soil mixture was amended with slow-release fertilizer (Osmocote; Scott's, Marysville, 14:14:14 nitrogen:phosphorous:potassium mixture was amended with slow-release fertilizer (Osmocote; Scott’s, Marysville, OH), and plants were watered daily.

The glasshouses consist of six modules structured as three blocks, each block having two modules of differing CO₂ concentrations (380 and 700 ppm). Containers were arranged in the modules according to their CO₂ and temporal cohort (i.e., eight plants in each of three temporal cohorts, in each of three glasshouse modules, at both low and high CO₂, for a total of 144 plants). Day/night temperatures were maintained at 26/21°C. Ambient glasshouse light levels were approximately 70% of full sun, supplemented with 6 hr of light daily (1000 to 1600 hr) from overhead metal halide lamps, thus allowing plants to experience natural variation in day length. Temperature, CO₂, and light were computer-controlled for all modules, and we used corn plants (*Zea mays*) to help maintain a constant CO₂ concentration in the low-CO₂ modules. In each module, temporal cohorts of ragweed plants were separated, and the positions of the containers within each treatment were randomized at intervals to minimize edge effects. Cohorts were grown at a foliar density of approximately nine plants per square meter. We recorded measurements of flower phenology and date of first pollen release for each ragweed plant throughout the experiment.

We chose five male floral spikes at random from each plant in the first two cohorts and three from each plant in the third cohort at each CO₂ level and placed a 5 cm × 25 cm polyethylene bag over each selected spike, similar to the procedure described in Ziska and Caulfield (2000). On one side of the bag near the bottom, we cut a small slit and placed the spike inside. The slit was then taped shut and the bag left to collect pollen shed by the spike, with the tops of the bags left open for ventilation. After pollen production had stopped, we measured the length of the bagged flower spikes, cut each at the base, and stored the spike in the collection bag at −20°C until ready for evaluation. Bags in which water accumulated due to watering or heavy condensation were discarded, leaving 477 individual inflorescences.

After senescence, we harvested plants over 3 days from 16 through 18 September. Plant height and number of inflorescences were recorded, the plants were cut at the base, and all flower spikes were removed and placed in bags separate from the vegetative material. We measured the length of each floral spike on each plant. Roots were washed clean of dirt and also placed in separate bags. All plant material was dried at 70°C for 48 hr, and we recorded separate dry weight measurements for all roots, flowers, and vegetative material.

For each bagged flower spike, pollen was recovered by twice repeated 30-sec vortexing in a wash solution (distilled water with 0.02% Tween 20) in 15 mL Falcon tubes, followed by 5-min centrifugation (2,500 rpm; relative centrifugal force = 600). Pollen recoveries from the spike and pollen rinsed from the polyethylene bag were combined in a total volume of 2.0 mL wash solution. We determined the number of pollen grains per spike by calculating the pollen concentration in the wash suspension from microscopic counts using a glass hemacytometer (Hausser Scientific, Horsham, PA).

For each inflorescence, we estimated pollen production, p, from an allometric model based on log inflorescence length, time of dormancy release, CO₂ concentration, total number of inflorescences, total weight of inflorescences, and days to anthesis:

\[
\log(p) = \mu + tr + f_{ij} + (al + t_{ij} + n_{ij} + c_{ij})q_{ij} + w_{ij} + a_{ij} + (a_{ij})j, \tag{1}
\]

where μ is a constant and j indexes each inflorescence of log length l on plant i with

Table 1. Regression coefficients for the model estimating whole-plant pollen productivity of *A. artemisiifolia*.
number of inflorescences $n$, total inflorescence weight $w_1$, and days to anthesis $a_2$ dormancy release at time $t$, and grown under CO2 concentration $c$. Additional interaction terms did not improve model prediction. We estimated whole-plant pollen production, $p$, as the sum of pollen production over all inflorescences on each plant.

We used a two-way factorial design with time of dormancy release crossed with CO2 treatment and CO2 nested within glasshouse wing to assess the responses to the timing of dormancy release and CO2, and we modeled estimated pollen count, inflorescence number, inflorescence weight, aboveground biomass, plant height, days to anthesis, and date of anthesis. Time was included as a fixed term. Glasshouse wing and CO2 within wing were included as random terms to permit broad inference. We included the time $\times$ CO2 interaction as a fixed term because plants were individually randomized.

**Results**

The impact of variability in the onset of spring under scenarios of ambient and elevated CO2 was assessed through several biomass (plant height, aboveground biomass), phenological (days to anthesis, anthesis date), and reproductive measures (number of inflorescences, inflorescence length, total weight of inflorescences, pollen production).

The model estimating whole-plant pollen production explained 62% of the variation in measured pollen counts from 477 inflorescences collected from 141 of 144 individual plants. Pollen production per inflorescence was most strongly associated with inflorescence length, number of inflorescences per plant, and days to anthesis (Table 1). The negative association between inflorescence number and pollen production suggests a tradeoff, with some plants producing fewer pollen-rich inflorescences and others producing more inflorescences each producing less pollen per unit length.

We examined the interaction of time of dormancy release and CO2 concentration, and the results are presented in Table 2. Significant time $\times$ CO2 interaction terms were found in each of estimated pollen count, inflorescence number, inflorescence weight, aboveground biomass, and plant height (marginally). CO2 treatment did not significantly affect days to anthesis or anthesis date.

We calculated least-square means for each level of time and CO2 along with 95% confidence limits for the measures of biomass, reproductive effort, phenology, and pollen productivity. Plants in early spring cohorts had significantly greater aboveground biomass and height than did the late cohort, as shown in Figure 1, with the greatest difference between early and late cohorts. Little additional gain in biomass or height was achieved between middle and early cohorts under either CO2 condition, perhaps indicating that near-maximal growth occurred in the longer growing seasons. However, in cohorts released from dormancy later, plants grown in elevated CO2 acquired significantly greater height and weight. Hence, elevated CO2 appears to have a greater impact on increasing biomass when plants are younger and/or smaller.

Earlier release from dormancy also increased reproductive effort measured by the number of inflorescences and inflorescence weight (Figure 2). There was a continuous trend toward a greater number of, and heavier, inflorescences in the middle and early cohorts at ambient CO2 levels. In the early cohort, there was no difference in reproductive effort for plants grown at ambient versus high CO2. Interestingly, at high CO2, plants from the middle cohort had the highest number and heaviest inflorescences. At high CO2, inflorescences were significantly heavier and more abundant in both the middle and later cohorts than at ambient CO2 levels.

We also examined the influence of growing season length and CO2 on phenological responses of days to anthesis and anthesis date (Figure 3). Photoperiodic control of flower initiation is well documented in *A. artemisiifolia* and is similar to many other late-summer–flowering plants. Therefore, little difference in the number of days to flowering (anthesis) and anthesis date was expected. Logically, plants released from dormancy earlier had a longer time until flowering. However, surprisingly, the anthesis date (date on which first pollen release was recorded) differed among the three cohorts. There was a consistent trend toward a later date of first
increase in earlier cohorts (Figure 4). At ambient CO2 levels, the simulated early spring cohort produced 54.8% more pollen compared with plants released from dormancy late. High CO2 did not further increase pollen production relative to ambient CO2 in the early cohort, but increased pollen production was observed in the middle (32.0% increase, \( p = 0.0506 \)) and late (55.0% increase, \( p = 0.0240 \)) cohorts.

Discussion

This study is the first to assess the potential impact of earlier arrival of spring, and the interaction with CO2, as expected with global warming and increased climate variability, on pollen productivity in allergenic plants. Based on the current rate of phenological advances (5 days/decade) (Rogers et al. 2003), the degree of advancement used in this study is similar to what might be expected three to six decades in the future. Our simulated effect of earlier spring dormancy release allowed ragweed plants to accumulate more resources through the season, thereby increasing biomass and reproductive effort. Plants in ambient CO2 released from dormancy earlier had increased height and weight, more and heavier inflorescences, and 54.8% higher pollen production compared with those released 30 days later. Increased temperatures, which would accompany earlier spring and elevated CO2 under future climate regimes, although not studied in these experiments, might also affect pollen production.

Because increasing atmospheric CO2 is assured for the next several decades, and it is unknown how CO2 might interact with climatic variables to influence plant responses, we also determined the additional interactive effects of elevated CO2 with variations in the onset of spring. We found that there was no additional advantage to plants in the earliest cohort grown under high CO2. However, the number and weight of inflorescences were significantly greater at high CO2 relative to ambient levels for plants in both the middle and late cohorts. Increased biomass and pollen production was also significantly higher in the late cohort at high CO2 levels. Hence, the reproductive disadvantage of a shorter growing season could be ameliorated when plants are grown in elevated CO2.

It is a well-known phenomenon of chamber studies that the advantage of elevated CO2 is greatest early in plant development but diminishes over time (Drake et al. 1997). In essence, plants exhibit acclimation to elevated CO2 with age (Long et al. 2004) or perhaps as a result of resource depletion due to the confines of growth within pots (Drake et al. 1997). We found the least difference in productivity between plants in ambient and elevated CO2 for the earliest cohort. Early-cohort plants in elevated CO2 may have had an early advantage but then acclimated over time, and/or the longer growing season may have been sufficient for ambient-CO2 plants to make up the early difference. In contrast, in the latest cohort with the shortest growing season—and hence the least amount of time for ambient-CO2 plants to make up the early difference in productivity—elevated-CO2 plants had significantly greater biomass, number and weight of inflorescences, and pollen production relative to ambient-CO2 plants. These results highlight the importance of examining the interactive effects of CO2 with other climate variables in order to understand the implications of climate change.

The climate variability that stems from global warming is a significant concern. Our results show that variability in the onset of spring elicits a strong increase in pollen production in early seasons at ambient CO2 concentrations. However, in elevated CO2, although pollen productivity is enhanced, it is less sensitive to variability in season onset. Hence, in future climates with elevated CO2, we predict pollen production will be just as robust in years with late springs as in years with early springs. Overall, pollen production in ragweed can be expected to increase significantly under predicted future climate conditions.

Our results are consistent with the findings of other greenhouse and chamber studies on ragweed that have shown a 60–90% increase in pollen productivity with elevated CO2 (700 or 600 ppm) compared with current ambient levels (Wayne et al. 2002; Ziska and Caulfield 2000). Of course, the ability to generalize results of closed environment experiments to natural field populations is an important issue; however, A. artemisiifolia also appears to be a strong competitor in mixed populations in elevated CO2 (Bazzaz and Garbutt 1988). In addition, similar results on pollen productivity have been found in field studies. In cities, because of proximity to industrial and vehicular sources, atmospheric CO2 concentrations and temperatures are much higher than in the surrounding rural areas (Idso et al. 2002). Using a naturally occurring gradient in Baltimore, where temperature and CO2 are elevated by 1.8–2.0°C and 30% (to ~500 ppm), respectively, compared with outlying areas, Ziska et al. (2003) found that in experimental ragweed plots, plants increased biomass and pollen production with the degree of urbanization. This brings to light two facts: Plants in the field are responding similarly to effects modeled in glasshouse experiments, and urban plants are currently experiencing changed atmospheric conditions that are altering their pollen productivity now, not decades into the future.

Both allergies and asthma have been increasing worldwide in recent decades, significantly above that expected from better diagnosing or increased reporting (von Mutius 1998). Although the trend may be showing early signs of leveling off (Hertzen and Haathela 2005; Lawson and Senthilselvan 2005), there still is a much greater proportion of the population that is vulnerable to allergen exposure than ever before. Ragweed pollen allergens are some of the most potent in North America, and roughly 10% of the population is sensitized (Gergen et al. 1987). Diesel particles from truck and vehicle exhaust have been shown to act synergistically with pollen allergens to exacerbate disease (Hauer et al. 2003) and are now thought to be an important factor in the recent rise in allergic disease (Riedl and Diaz-Sanchez 2005). Hence, an important question is whether greater ragweed pollen production (with or without diesel particle coexposure) will lead to an increase in the frequency or severity of asthma and allergy symptoms, or to new sensitizations and a further increase in development of allergic disease.

Conclusion

The effects of global warming are complex, but studies of their impact on biotic communities clearly point toward secondary effects that could be detrimental to human health. Our study of A. artemisiifolia under conditions that simulate future levels of atmospheric CO2 and increased temperatures shows that one effect—increased production of allergenic pollen—could strongly affect the significant proportion of the population with pollen allergies as climate change progresses. Because the results of this study suggest that, under future conditions of global warming
and elevated CO₂, pollen seasons will be more intense and could start earlier than expected, pollen forecasting and pollen avoidance strategies for sensitized individuals will be particularly important. Finally, we emphasize the importance of studying interactions between multiple predicted climate change parameters, in this case, the interactive effects of elevated CO₂ and variability in the onset of spring. Our study suggests that under future predicted greenhouse gas emissions and associated climate conditions, either an early spring onset or variability in spring onset along with elevated CO₂, there will be an overall increase in ragweed pollen production.
