BACKGROUND: Previous literature suggests an association between organochlorines and behavioral measures in childhood, including inattention.

OBJECTIVE: This study was designed to assess whether prenatal organochlorine exposure is associated with measures of attention in early infancy.

METHODS: We investigated an association between cord serum polychlorinated biphenyls (PCBs) and p,p’dichlorodiphenyl dichloroethene (DDE) levels and measures of attention from the Neonatal Behavioral Assessment Scale (NBAS) in a cohort of 788 infants born 1993–1998 to mothers residing near a PCB-contaminated harbor and Superfund site in New Bedford, Massachusetts.

RESULTS: Medians (ranges) for the sum of four prevalent PCB congeners and DDE levels were 0.19 (0.01–4.41) and 0.30 (0–10.29) ng/g serum, respectively. For the 542 subjects with an NBAS exam at 2 weeks, we observed consistent inverse associations between cord serum PCB and DDE levels and NBAS measures of alertness, quality of alert responsiveness, cost of attention, and other potential attention-associated measures including self-quieting and motor maturity. For example, the decrement in quality of alert responsiveness score was –0.51 (95% confidence interval, –0.99 to –0.03) for the highest quartile of exposure to the sum of four prevalent PCB congeners compared with the lowest quartile. We found little evidence for an association with infant orientation, habituation, and regulation of state, assessed as summary cluster measures.

CONCLUSIONS: Our findings provide evidence for an association between low-level prenatal PCB and DDE exposures and poor attention in early infancy. Further analyses will focus on whether organochlorine-associated decrements in attention and attention-related skills in infancy persist in later childhood.

Organochlorines, including polychlorinated biphenyls (PCBs) and p,p’dichlorodiphenyl dichloroethene (DDE), the major degradation product of p,p’dichlorodiphenyl trichloroethane (p,p’DDT), though banned in the U.S. in the 1970s, are highly persistent in the environment and in human tissue. These contaminants cross the placenta and have been associated with reduced birth size (Fein et al. 1984; Hertz-Picciotto et al. 2005; Longnecker et al. 2001; Sagiv et al. 2007) and effects on subsequent neurodevelopment (Schantz et al. 2003).

Several previous studies have investigated the association between prenatal PCB exposures and behavior in infancy using the Neonatal Behavioral Assessment Scale (NBAS) (Jacobson et al. 1984a; Lonky et al. 1996; Rogan et al. 1986; Stewart et al. 2000). These studies, which summarize the NBAS scores using seven summary cluster measures developed by Lester et al. (1982) and later revised by Jacobson et al. (1984b), found the most consistent associations with increased number of abnormal reflexes (particularly hyporeflexia); in addition, decreased autonomic maturity and habituation, and, less commonly, poorer range of state scores were found in association with PCB exposures. Studies have also found associations between PCBs and infant visual recognition memory, potentially an early indicator of attention, using the Fagan Test of Infant Intelligence (Darvill et al. 2000; Jacobson et al. 1985).

Early life experience (including prenatal exposures) and health status are increasingly recognized as having enormous potential to affect subsequent childhood and, even adult, health (Kuh et al. 2003). However, behavioral or related functional health outcomes are difficult to measure in early infancy; there are few tests available for this age group, and generally such assessments have limited reproducibility and poor long-term predictive value (Gorski et al. 1987). Although an efficient data reduction technique, the seven summary NBAS clusters may not detect important behavior patterns captured by individual NBAS items.

For the current study, we hypothesized a specific association between prenatal organochlorine exposure and measures of attention in early infancy, and used individual NBAS items to characterize young infants’ attention skills. Previous literature reports associations between PCBs and attention among school-age children and adults (Grandjean et al. 2001; Jacobson and Jacobson 1996, 2003; Peper et al. 2005; Vreugdenhil et al. 2004). To investigate whether these associations could be detected in early infancy, we conducted a prospective cohort study of cord serum organochlorines and attention-related outcomes as measured by the NBAS among infants born to mothers residing near a PCB-contaminated harbor.

Materials and Methods

Study population. Study participants were a subset of infants from a birth cohort whose mothers resided adjacent to a PCB-contaminated harbor in New Bedford, Massachusetts, and were recruited at the time of the infant’s birth between 1993 and 1998. The parent cohort includes 788 mother–infant pairs participating in ongoing studies of prenatal PCB and organochlorine pesticide exposure and subsequent infant and child development. The cohort was recruited from a local hospital with approximately 2,000 births per year, about 10% of whom were available for recruitment during times when a study examiner was on site, and met study eligibility criteria. Mother–infant pairs were eligible to participate if the mother was ≥18 years of age, had lived in one of four towns (New Bedford, Acushnet, Fairhaven, Dartmouth) adjacent to the contaminated New Bedford Harbor for at least the duration of her pregnancy, and spoke English or Portuguese. Infants too ill to undergo neonatal examination or born by cesarean section were excluded. Preterm infants (<37 weeks gestation) and multiple births were excluded from the current analysis.

**Laboratory measurements of exposure.**

Cord blood samples for organochlorine analyses were collected at the infant's birth; the serum fraction was removed after centrifugation and stored at −20°C. All sample analyses were performed by the Harvard School of Public Health Organic Chemistry Laboratory (Boston, Massachusetts). Laboratory personnel were blinded to infant outcomes. Cord serum samples were analyzed for 51 individual PCB congeners and two chlorinated pesticides [p,p’-DDE and hexachlorobenzene (HCB)]. Laboratory analytic methods and quality control procedures are described elsewhere (Korrick et al. 2000). Briefly, liquid–liquid extraction was used according to procedures developed by the Centers for Disease Control and Prevention with modifications to conform to ultratrace-level analyses (Korrick et al. 2000). Extracts were analyzed by gas chromatography with electron capture detection on a Hewlett-Packard 5890 Series II GC (Hewlett Packard, Palo Alto, CA) with temperature and pressure programming capabilities and a split/splitless injector. Samples with possible phthalate contamination or a coeluting substance detected in blanks were checked by confirmatory analyses on a Hewlett-Packard 6890 GC with a Micro-ECD and a capillary column of different polarity. Where results differed, the lower value—considered more accurate because it indicated separation of the PCB congener from an interfering coeluting peak—was reported (Erickson 1997).

Quantitation was based on the response factor of each individual PCB congener or pesticide relative to an internal standard. PCB concentrations were reported as individual congeners, after the amount of analyte in the procedural blank was subtracted, and as the sum of all congeners assayed (ΣPCB) in units of nanograms per gram serum. Lipid content could not be determined for study subjects because of insufficient sample volume (1.5–4 mL) and was therefore measured for 12 randomly selected cord bloods from discarded, anonymous samples collected at the study recruitment site; values were reproducible (1.7 ± 0.3 g/L) and consistent with lipid content in cord blood reported elsewhere (1.8 ± 0.7 g/L) (Denkins et al. 2000).

The method detection limits (MDLs) for individual PCBs ranged from 0.002 to 0.04 ng/g, with most MDLs < 0.01 ng/g; respective MDLs for DDE and HCB in serum were 0.07 and 0.02 ng/g (Korrick et al. 2000). Ninety-six percent of samples had DDE levels above the MDL; from < 1% (congener 22) to 91% (congener 153) of samples had PCB congeners above the MDL (Korrick et al. 2000). Where no measurable quantity of analyte was detected, a value of zero was used in our analyses. We used quantifiable values below the detection limit to optimize statistical power and avoid biased exposure estimates associated with censoring at the MDL (Kim et al. 1995). Reproducibility of serum analyses was good; the ΣPCB within-batch coefficient of variation (CV) was 3% and the between-batch CV was 20% over the 5 years of analysis, with similar performance for pesticides.

Cord blood samples for lead measurement were analyzed at the Harvard School of Public Health Trace Metals Analysis Laboratory (Boston, Massachusetts). Samples were collected at birth in EDTA-containing Vacutainer tubes for trace metal analyses. Analyses employed isotope dilution inductively coupled plasma mass spectrometry (Sciex Elan 5000; PerkinElmer, Norwalk, CT) with standard instrument operating and data collection parameters. Quality control and assurance procedures included analyses of procedural blanks, duplicates, spiked samples, and standard reference material to monitor for contamination, accuracy, and recovery rates. Recovery rates for QC and spiked samples were 90–110%, and precision was < 5%. The detection limit was 0.02 µg/dL.

**Neonatal outcome assessment.** Newborns were examined twice with the NBAS (Brazelton and Nugent 1995). The first assessment took place between the first and third days of life (referred to as the birth exam), and the second was administered between 5 and 22 days, 80% of which fell between 8 and 20 days, (referred to as the 2-week exam). The NBAS assesses the infant’s behavioral capacities, including his or her ability to respond to the environment, such as the ability to orient and habituate to visual or auditory stimuli, both animate and inanimate; the quality of motor tone and activity levels; and the infant’s level of state regulation (i.e., amount of crying and the infant’s capacity to regulate his or her asleep, alert, crying states). The NBAS exam takes approximately 30 min to administer and contains 28 behavioral items, 18 elicited items (including neonatal reflexes), and up to 9 supplementary items, designed to capture the quality of newborn behavioral responsiveness. Each of the NBAS behavioral items is assigned a score (ranging from 1 to 9), according to established scoring criteria, with a higher score typically indicating better performance and a lower score indicating poorer performance (there are some items in which the opposite is the case or where the midpoint is optimal). Neonatal assessments were performed by three study staff members trained in administration and scoring according to the inter-rater reliability criteria established by the NBAS manual (Brazelton and Nugent 1995). Interobserver scoring agreement was calculated before the beginning of the study and then at least biannually thereafter; inter-rater agreement was established at ≥ 90%.

The focus of the current study was infant attention, and we analyzed eight a priori selected NBAS behavioral items to identify the infant’s capacity for attention or abilities potentially associated with attention, such as state regulation and motor maturity. Table 1 lists all outcomes analyzed. The individual behavioral items analyzed for this study were alerterness, consolability, self-quieting activity, hand-to-mouth facility, irritability, elicited and spontaneous activity, and motor maturity. NBAS supplementary items were designed to evaluate the infant’s ability to cope with the examination and maintain an alert state (Brazelton and Nugent 1995). Two supplementary items measuring alertness were selected for inclusion in the analysis: a) quality...
of alert responsiveness, which assesses the level of “processing” alertness as opposed to a simple awake “eyes open” state, and b) cost of attention, which measures the degree to which the motor and physiologic systems were stressed as a result of the infant’s efforts to attend to the stimuli.

As a secondary analysis we also analyzed three of six previously defined behavioral clusters (Jacobson et al. 1984b; Lester et al. 1982).

of Harvard School of Public Health and Brigham and Women’s Hospital in Boston and of St. Luke’s Hospital, the New Bedford site of Southcoast Hospitals Group, New Bedford. Written informed consent was obtained from all participating families before study evaluation.

**Results**

Among the 788 infants included in the initial study population, we excluded 6 twins, 24 singleton preterm births, and 36 infants without serum organochlorine measures. Of the remaining 722 infants, 539 had measures for the birth NBAS assessment, 542 for the 2-week assessment, and 408 infants were administered both exams. Table 2 shows characteristics for the 542 mother–infant pairs with the 2-week exam. Mothers were mostly white, > 80% graduated from high school, more than a third were low income (household income < $20,000 per year), a little more than half were married, and almost a third smoked during their pregnancy. The mean gestational age at birth and mean birth weight were 39.8 weeks and 3,401 g, respectively, and 37% of infants were breast-fed for at least 1 month. The median cord serum level for subjects included in this analysis was 0.19 ng/g (range, 0.01–4.41 ng/g serum) for the sum of four prevalent PCB congeners and 0.30 ng/g (range, 0–10.27 ng/g serum) for DDE.

Figure 1 shows inverse associations for the two PCB congener groups as well as DDE and measures of attention, including alertness,
quality of alert responsiveness, and cost of attention. Though the \( p \)-for-trend was statistically significant for just one-third of these associations, most of the graphs show a consistent decline in attention-related scores with increasing quartile of exposure.

There were less consistent associations between cord serum organochlorines and state-related items, including consolability, self-quieting activity, and hand-to-mouth facility (Figure 2). We observed inverse associations between only a few organochlorines and state-associated outcomes, and predominantly for self-quieting activity. Irritability was associated with the sum of mono-ortho TEF-weighted PCB congeners (TEQ) and DDE (Figure 3), as shown by increasing risk ratios for high versus normal irritability across quartiles of cord serum levels and significant or near significant \( p \)-values for trend. There was less evidence for increased risk of never being in the appropriate state to respond to orientation (missing data for all orientation items) across quartiles of cord serum PCBs, TEQ, and DDE.

Less consistent associations were also found for motor outcomes, though motor maturity did appear to decline with increasing cord serum PCB, TEQ, and DDE levels (Figure 4). There appeared to be a positive association between cord serum organochlorines and spontaneous activity. There were no consistent associations between organochlorines and any of the three cluster measures (orientation, habituation, and regulation of state; data not shown).

The general pattern of these findings was unchanged when a narrower window of time (10–17 days after birth) was used for the 2-week exam. Findings also remained unchanged when more recent TEF weights were applied (Van den Berg et al. 2006).

Subjects had to have data for both the birth and the 2-week exams to be included in the failure-to-recover analysis. Depending on the item, between 59 and 358 subjects were included. There were no consistent patterns found for PCBs, TEQ, or DDE and failure to recover for any of the NBAS outcomes.

**Figure 2.** Associations and 95% confidence intervals (CIs) between cord serum levels of the sum of four PCB congeners (118, 138, 153, 180), the sum of mono-ortho TEF-weighted PCB congeners (TEQ), and DDE, and 2-week NBAS continuous measures of state (consolability, self-quieting, and hand-to-mouth facility), adjusted for infant’s age at exam, birth year, time since last feeding, NBAS examiner, and maternal age, education, breast-feeding, household income, and OB risk score for term infants born in New Bedford, 1993–1998.

**Figure 3.** Associations and 95% confidence intervals (CIs) between cord serum levels of the sum of four PCB congeners (118, 138, 153, 180), the sum of mono-ortho TEF-weighted PCB congeners (TEQ), and DDE, and 2-week NBAS dichotomous measures of state (irritability [high score 7–9 vs. normal score 4–6] and never in state to do orientation items [all orientation items missing vs. data on at least one orientation item]), adjusted for infant’s age at exam, birth year, time since last feeding, NBAS examiner, and maternal age, education, breast-feeding, household income, and OB risk score for term infants born in New Bedford, 1993–1998.

**Discussion**

Our approach to analyzing the NBAS in the current study was different than previous studies that used the traditional seven summary cluster measures developed by Lester et al. (1982) and later revised by Jacobson et al. (1984b). These previous studies found associations between organochlorines (primarily PCBs) and increased number of abnormal reflexes, decreased autonomic maturity and habituation, and, less commonly, range of state (Jacobson et al. 1984a; Lonky et al. 1996; Rogan et al. 1986; Stewart et al. 2000).

For this analysis we hypothesized an association between PCBs and attention-associated behaviors in infancy. Previous literature suggests that prenatal PCB exposures affect attention later in childhood (Grandjean et al. 2001; Jacobson and Jacobson 1996, 2003; Peper et al. 2005; Vreugdenhil et al. 2004). A study of children born to Lake Michigan fish
consumers reported associations between pre-
natal PCB exposure and poorer performance 
on a Digit Cancellation task, which indicates 
difficulty with focused attention and concen-
tration, among 11-year-old children who had 
not been breast-fed (Jacobson and Jacobson 
2003). Associations were also reported among 
these same children between PCBs and 
poorer freedom from distractibility, a subscale 
of the Wechsler Intelligence Scales for 
Children (Jacobson and Jacobson 1996). 
Associations were not detected, however, 
between PCBs and measures of sustained 
attention among children in this study at 
11 years of age, or at an earlier assessment made 
at 4 years of age (Jacobson and Jacobson 
Islands study found associations between 
PCBs and attention measured by a continu-
ous performance test among children 7 years 
of age only in the context of high mercury 
exposure, suggesting a potential interaction 
between these contaminants (Grandjean et al. 
2001). A Dutch study found associations 
between PCBs and sustained attention 
among 9-year-olds, measured by a continuous 
performance tests (Vreugdenhil et al. 2004). 
Another study among adults exposed to PCBs 
from a contaminated building found associa-
tions with attention as well as distractibility 
(Peper et al. 2005).

The present analysis was designed to 
investigate whether an association between 
organochlorines and attention could be 
detected in early infancy. We therefore focused 
on a priori selected individual NBAS items, 
including supplementary items (Braetelton and 
Nugent 1995), as well as cluster measure out-
comes that we believe reflect attention-associ-
ated skills. In addition, there is substantial 
overlap between childhood attention disorders 
[for example, the diagnosis of attention deficit 
hyperactivity disorder (ADHD)] and the diag-
nosis of motor impairment as occurs, for exam-
ple, in developmental coordination disorder 
(Gillberg 1998; Kadesjo and Gillberg 1998). 
Independent of co-morbidities, children with 
ADHD may also have poor movement ability 
(Gillberg 2003; Pitcher et al. 2003), so NBAS 
measures of motor function were included in 
our analyses.

Our results show consistent inverse associ-
ations between PCB, TEQ, and DDE cord 
surface levels and attention-related NBAS 
outcomes, including alertness, quality of alert 
responsiveness, and cost of attention 
(Figure 1). The NBAS supplementary items 
analyzed (quality of alert responsiveness, cost 
of attention) were designed to capture qualita-
tive aspects of the infant’s ability to attend to 
visual and auditory stimuli. For example, qual-
ity of alert responsiveness is designed to mea-
sure “processing” alertness, not just simple 
awake, eyes-open states. Given this specified 

purpose, it is notable that the association with 
cord serum PCBs and TEQ was particularly 
strong for supplementary items (Figure 1). 
These supplementary items were not included 
in the NBAS manual until 1995, well after 
most previous studies of PCBs and NBAS had 
been conducted, thereby affording an oppor-
tunity to assess a more inclusive set of atten-
tion measures in this analysis than had been 
possible previously.

Inverse associations were less pronounced 
for state- and motor-associated outcomes 
(Figures 2 and 4). We found little evidence 
for an association with the three cluster out-
comes analyzed, which did not corroborate 
results of the previous studies conducted in 
Oswego, New York, and in North Carolina 
that found associations between PCBs and 
the habitation cluster (Rogan et al. 1986; 
Stewart et al. 2000).

The positive association observed between 
organochlorines and spontaneous activity is 
consistent with hyperactivity–impulsivity 
observed in experimental animal models of 
early-life PCB exposure (Berger et al. 2001; 
Holene et al. 1998; Rice 2000). Impulsive 
responding has been reported among humans 
exposed to PCBs. A study designed to associ-
ate response inhibition from attention found 
associations between PCBs and impulsive 
responding among children 8 and 9.5 years of 
age but not with sustained attention (Stewart 
et al. 2005). These results are consistent with 
earlier studies of this cohort in which an asso-
ciation between PCBs and response inhibi-
tion was reported at 4.5 years of age (Stewart 
et al. 2003). The Michigan study also found 
associations between PCBs and impulsivity 
among 11-year-olds who had not been breast-
fed (Jacobson and Jacobson 2003)

We examined whether organochlorines 
impaired the infant’s ability to recover from 
the birth experience by assessing changes in 
performance between the birth exam and the 
2-week exam. Recovery is informative of an 
infant’s ability to cope and adapt to the 
extrauterine environment, and was an origi-
nally intended application of the NBAS 
(Braetelton and Nugent 1995). Our findings 
for recovery were limited in power, however, 
because data were missing for either exam 
(both were required).

PCBs are a heterogeneous mixture of con-
geners, potentially with different toxicologic 
modes of action. A considerable strength of this 
study was our ability to measure up to 51 dif-
ferent PCB congeners. Though not presented 
in the results, effect sizes for the sum of 51 
congeners were similar, though slightly attenuated, 
compared with the sum of 4 PCBs; these 
4 congeners are more prevalent and likely mea-
ured with more accuracy than the sum of 51 
congeners, which may explain the more attenu-
ated effects found for the sum of 51 congener.

The correlation between the sum of 51 
and the sum of 4 congeners was also quite high (0.91), 
and we therefore presented only the sum of the 
4 congeners, which we believe adequately repre-
sents the sum of all congeners.

To take advantage of congener-specific 
information, we grouped congeners into 
structurally related classes—dioxin-like PCBs
(TEQ) and non-dioxin-like PCBs (sum of 4 congeners)—that represented potentially different biologic mechanisms in their effect on neurodevelopment. That we did not find a difference in the effect of these two groups on NBAS outcomes was not surprising, because these groups were highly correlated in our study. Categorizing PCBs into such congener classes is important, however, for understanding the mode of action of these different compounds and their relative neurotoxic potency, both of which have implications for risk assessment (Schantz et al. 2003).

A barrier to understanding congener-specific effects stems from lack of knowledge of the biologic mechanism for the observed effect of PCBs on attention. Associations of PCBs with ADHD-like behaviors have been observed in rodents and nonhuman primates, however (Berger et al. 2001; Holene et al. 1998; Rice 2000). PCBs can disrupt dopaminergic functions, as reflected in alterations in dopamine levels in cell culture and in the brains of laboratory animals (Seegal et al. 1997, 2002). This is one possible mechanism whereby PCBs may affect attention-related behaviors, since decreases in cellular dopamine have been correlated with attention disorders such as ADHD (Faraone and Biederman 1998). PCBs and their hydroxylated metabolites can disrupt thyroid homeostasis, another potential mechanism of ADHD-like effect (Hauser et al. 1998; Kimura-Kuroda et al. 2007). For example, early-life hypothyroidism is associated with subsequent ADHD-like behaviors in animal models (Negishi et al. 2005; Siesser et al. 2006).

There is evidence that variations in thyroid indices or resistance to thyroid hormone may be associated with ADHD-like behavior in humans (Alvarez-Pedreiro et al. 2007; Hauser et al. 1993; Matotchk et al. 1996; Stein et al. 1995), but this association has not been consistently demonstrated (Stein and Weiss 2003; Toren et al. 1997).

Serum PCB levels in the New Bedford study population were generally lower than in other birth cohort studies of PCB exposure and likely reflect more general population levels. A comparison of 10 studies of diverse locations and birth years found that the New Bedford cohort was at the low range of PCB levels (represented by PCB congener 153) relative to other populations (Longnecker et al. 2003). This would have reduced power to detect associations; that we still found consistent associations with attention indicates potential for effects at low PCB levels found in the general population.

It is unclear how much can be learned of an individual’s long-term behavior from observations in infancy. Previous studies find that infant attention is predictive of intelligence in childhood and adolescence (Sigman et al. 1986, 1997). A study of temperament in infancy (5–6 months) and toddlerhood reported significant prediction of impulsivity and inattention among 8-year-old children (Olson et al. 2002). Other studies did not find infant temperament alone to be predictive, but rather that the combination of infant temperament with parental attitude or perception was predictive of behavioral problems later in childhood (Cameron 1978; Oberklaid et al. 1993; Wasserman et al. 1990). These studies suggest that infant temperament and the interaction between the infant and his or her environment are important determinants of later behavioral outcomes.

How well the NBAS predicts attention later in childhood is also uncertain. Some studies report poor correlation between NBAS and behavioral outcomes later in childhood (Risholm-Morhander 1989; Sameroff et al. 1978), whereas another study found behavioral and reflex clusters to be good predictors of later developmental disabilities among a high-risk population (Ohgi et al. 2003). An important area for future study will be to examine whether these PCB-associated decrements in attention-related skills in infancy are transient or predict attention-related problems later in childhood.

We did not assess maternal IQ at birth, though we did measure maternal IQ with the Kaufman Brief Intelligence Test (Kaufman and Kaufman 1990) on a subset of the children that were available for testing at 8 years old. When we included maternal IQ as a covariate the exposure–outcome effect was slightly stronger, although the precision was reduced because of the smaller number of children on whom maternal IQ was available. In addition, maternal IQ was not predictive of any of the analyzed NBAS items. Final estimates are therefore reported without adjustment for maternal IQ.

This analysis was limited to subjects who were administered an NBAS exam (539 had an exam around the time of birth, 542 had an exam 1–3 weeks after birth, and 408 had both exams). This process resulted in reduced study power, particularly for the recovery analysis, which required both exams. However, we do not expect that it resulted in bias as organochlorine levels and covariates for these groups were very similar (data not shown).

Every effort was made to schedule infant exams in the second week of life; however, it was difficult to examine young infants at such a narrow age range in a nonclinical, population-based study. The use of a broad time window for the 2-week exam may have introduced some random error into our estimates. Exposure effect estimates for NBAS exams conducted for a more narrow window (10–17 days) were very close to estimates from the broader time window (5–22 days), suggesting that including a broader age range did not bias our results.

We evaluated a number of outcomes for this analysis as well as several categories of PCB congeners and DDE. Multiple comparisons were therefore performed and may be a limitation when interpreting positive findings. Our observation of internal consistency, however, particularly for the attention-associated outcomes, suggests that our findings were probably not attributed to chance.

In summary, we found evidence for an association between low-level prenatal organochlorine exposure measures and attention in early infancy. This observation is particularly notable given both the low-level PCB exposure in our study population and the limitations of behavioral assessments in young infants. The longitudinal design of the New Bedford cohort will enable us to further determine whether a) poor attention-associated skills in early infancy (as measured by the NBAS) persist in later childhood—that is, whether a behavioral pattern seen in infancy predicts later childhood behavioral skills; and b) the observed association of prenatal organochlorine exposure with attention in infancy persists in later childhood. Identifying attention-related deficits as early as infancy, and identifying potentially remediable risk factors for such deficits (for example, PCB exposure), allows for early intervention (and ultimately prevention efforts), which may be important for promoting healthy subsequent neurodevelopment.
