(Dated: June 16, 2011)

Quantum noise correlations have been employed in several areas in physics including condensed matter, quantum optics and ultracold atom to reveal non-classical states of the systems. So far, such analysis mostly focused on systems in equilibrium. In this paper, we show that quantum noise is also a useful tool to characterize and study the non-equilibrium dynamics of one dimensional system. We consider the Ramsey sequence of one dimensional, two-component bosons, and obtain simple, analytical expressions of time evolutions of the full distribution functions for this strongly-correlated, many-body system. The analysis can also be directly applied to the evolution of interference patterns between two one dimensional quasi-condensates created from a single condensate through splitting. Using the tools developed in this paper, we demonstrate that one dimensional dynamics in these systems exhibit the phenomenon known as ”prethermalization”, where the observables of non-equilibrium, long-time transient states become indistinguishable from those of thermal equilibrium.

I. INTRODUCTION

Probabilistic character of Schrödinger wavefunctions manifests itself most directly in quantum noise. In many-body systems, shot-to-shot variations of experimental observables contain rich information about underlying quantum states. Measurements of quantum noise played crucial role in establishing nonclassical states of photons in quantum optics[1], demonstrating quantum correlations and entanglement in electron interferometers[2], and verifying fractional charge of quasi-particles in quantum Hall systems[3–5]. In atomic physics so far, noise experiments focused on systems in equilibrium. Recent work includes analysis of counting statistics in atom lasers[6], establishing Hanbury-Brown-Twiss effect for both bosons and fermions[7], analysis of quantum states in optical lattices[8–12], observation of momentum correlations in Fermi gases with pairing[13] and investigation of thermal and quantum fluctuations in one and two dimensional condensates[14–21].

In this paper we demonstrate that analysis of quantum noise should also be a powerful tool for analyzing non-equilibrium dynamics of strongly correlated systems. Here we study the two equivalent dynamical phenomena: one given by the interaction induced decoherence dynamics in Ramsey type interferometer sequences for two component Bose mixtures in one dimension[22], and another given by the evolution of interference patterns of two one dimensional condensate created through the splitting of a single condensate[23–24]. We obtain a complete time evolution of the full distribution function of the amplitude of Ramsey fringes or interference patterns. In the case of Ramsey fringes, the average amplitude of Ramsey fringes measures only the average value of the transverse spin component. On the other hand, full distribution functions are determined by higher order correlation functions of the spins. Hence full distribution functions contain considerably more information about the time evolution of the system[21–27] and provide a powerful probe for the nature of the quantum dynamics under study. In particular, we use the simple expressions of full distribution functions to demonstrate the phenomena of ”prethermalization” in these one dimensional systems, where observables in non-equilibrium long-time transient states become indistinguishable from those in thermal equilibrium states.

One dimensional systems with continuous symmetries, including superfluids and magnetic systems, have a special place in the family of strongly correlated systems. Quantum and thermal fluctuations are so extreme that long range order is not possible in equilibrium. Such systems can not be analyzed using standard mean-field approaches, yet they can be studied through the application of methods specific to one dimension such as exact Bethe ansatz solutions[28–39], effective description using Tomonaga-Luttinger and sine-Gordon models[40–45], and numerical analysis using density-matrix renormalization group(DMRG) and matrix product state (MPS) methods[46]. Such systems are often considered as general paradigms for understanding strongly correlated systems. One dimensional systems also give rich examples of integrable systems, where due to the existence of infinite number of conserved quantities, equilibration does not take place[47–49]. Hence the problem we consider in this paper is important for understanding fundamental issues such as the quantum dynamics of strongly correlated systems and equilibration/non-equilibration of many-body systems, as well as for possible applications of spinor
condensates in spectroscopy, interferometry, and quantum information processing [50–52].

Our work is motivated by recent experiments of Widera et al. [22] who used two hyperfine states of $^{87}\text{Rb}$ atoms confined in 2D arrays of one dimensional tubes to perform Ramsey type interferometer sequences. They observed rapid decoherence of Ramsey fringes and the near absence of spin echo. Their results could not be explained within the single mode approximation which assumes a macroscopic Bose condensation into a single orbital state, but could be understood in terms of the multi-mode Tomonaga-Luttinger type model. Yet the enhanced decoherence rate and suppression of spin echo do not provide unambiguous evidences for what the origin of decoherence is. In this paper, we suggest that the crucial evidence of the multi-mode dynamics as a source of decoherence should come from the time evolution of the full distribution functions of the Ramsey fringe amplitude. Such distribution functions should be accessible in experiments on Atom Chips [14, 53–56] from the analysis of shot-to-shot fluctuations.

This paper is organized as follows. In Section II, we describe two physically distinct, but yet mathematically equivalent, dynamics in one dimensional systems, namely, the dynamics of spins in a Ramsey sequence and the dynamics of phase and contrast in interference patterns between two split condensates created from a single condensate. We start with illustrating the basic physics governing the dynamics studied in this paper, and give a summary of the central results including the prediction of prethermalization phenomena. The formal descriptions of the details of the theory for spin dynamics in Ramsey sequence start from Section III where we give the Hamiltonian of the one dimensional system based on Tomonaga-Luttinger approach. In Section IV, we derive the analytical expression for the time evolution of the full distribution function for a simple case in which charge and spin degrees of freedom decouple. This decoupling limit gives a good approximation to the experimental situation of Widera et al. [22]. A short summary of the result in this decoupling limit has been already reported in Ref [52]. More general case in which spin and charge degrees of freedom mix is studied in Section V. Such mixing introduces the dependence of spin distribution functions on the initial temperature of the system. All the results obtained in Sections IV and V can be extended to the study of the dynamics of interference patterns, using the mapping described in Section III. The details of the dynamics of phases and contrasts in interference patterns between split condensates is studied in Section VI. We demonstrate the prethermalization phenomena and show that the interference contrasts of split condensates in a steady state have indistinguishable distributions from those of thermal condensates at some effective temperature $T_{\text{eff}}$. We conclude in Section VII with a discussion of possible extensions of this work.

II. DESCRIPTION OF ONE DIMENSIONAL DYNAMICS AND THE SUMMARY OF RESULTS

A. Ramsey Dynamics

In this paper, we study the dynamics of one dimensional, interacting two-component Bose mixtures in the Ramsey-type sequence. In analogy with spin-1/2 particles, we refer to one component to be spin-up and the other component to be spin-down. In the experiment of cold atoms in Ref [22], two hyperfine states are used for these two components. In the following, we consider a generic situation where there is no symmetry that relates spin-up and spin-down. Unlike fermions with spin-1/2, there is no SU(2) symmetry. In a typical experimental setup with cold atoms, there is a harmonic confinement potential along the longitudinal direction of condensates, but here we assume the absence of such a harmonic trap potential. Our consideration gives a good approximation for the central region of cold atom experiments in the presence of such potentials.

Ramsey-type sequence is described as follows(Figure 1):

1. All atoms are prepared in spin up state at low temperature
2. $\pi/2$ pulse is applied to rotate the spin of each atom
3. $t$ pulse is applied to evolve for time $t$
4. Imaging step (4) is omitted in the illustration.

FIG. 1: Ramsey sequence for one dimensional system with two component bosons considered in this paper. (1) All atoms are prepared in spin up state; (2) $\pi/2$ pulse is applied to rotate each atom into the $x$ direction; (3) spins freely evolve for time $t$. In actual experiments, final $\pi/2$ pulse is applied to measure the $x$ component of spin. The imaging step (4) is omitted in the illustration. In this paper, spin operators refer to the ones before the final $\pi/2$ pulse.
3. Spins evolve for time $t$

4. Spins in the transverse direction ($x - y$ plane) are measured

In a typical experimental situations\cite{22}, the last measurement step is done by applying a $\pi/2$ pulse to map the transverse spin component into $z$ direction, which then can be measured. In the following discussions, we describe the dynamics in the rotating frame of Larmor frequency in which the chemical potentials of spin-up and spin-down are the same in the absence of interactions. In this frame, the evolution of spins in the third step is dictated by the diffusion dynamics coming from interactions. Unlike the conventional use of the Ramsey sequence in the context of precision measurements, here we employ the Ramsey sequence as a probe of correlation functions in one dimensional system.

The description of the spin dynamics starts from the highly excited state prepared after the $\pi/2$ pulse of step 2. The subsequent dynamics during step 3 crucially depends on the nature of excitations in the system. In particular, the dynamics of two-component Bose mixture in one dimension is quite different from those in three dimension. In three dimensions, bosons form a Bose-Einstein condensate (BEC) at low temperature, and particles occupy a macroscopic number of $k = 0$ mode. Then, the spin diffusion of three dimensional BEC is dominated by the spatially homogeneous dynamics coming from the single $k = 0$ mode at sufficiently low temperatures. On the other hand, bosonic systems in one dimension do not have the macroscopic occupancy of the $k = 0$ mode, and their physics is dominated by the strong fluctuations, to the extent that the system cannot retain the long range phase coherence even at zero temperature\cite{11}. Thus, the spin dynamics of one dimensional bosonic system necessarily involves a large number of modes with different momenta and the spin becomes spatially inhomogeneous during the step 3 above.

Such dynamics unique to one dimension can be probed through the observation of transverse spin components in the fourth step. Since we aim to capture the multi-mode nature of the dynamics in one dimension, we consider the observation of spins at length scale $l$, given by

$$S^a_l(t) = \int_{-l/2}^{l/2} dr \tilde{S}^a(r,t)$$

(1)

where $\tilde{S}^a(r,t)$ with $a = x, y$ are the transverse components of spin operators after time evolution of step 3 of duration $t$. We assume that $l$ is much larger than the spin healing length $\xi$, and much smaller than the system size $L$ to avoid finite size effects. Furthermore, we assume that the number of particles within the length $l$, $N_l$, is large, so that the simultaneous measurements of $\hat{S}^x_l(t)$ and $\hat{S}^y_l(t)$ are in principle possible. For large $N_l$, the non-commutativity of $\hat{S}^x_l$ and $\hat{S}^y_l$ gives corrections of the order of $1/\sqrt{N_l}$ compared to the average values. In this situation, it is also possible to measure the magnitude of transverse spin components, $\hat{S}^z_l = \sqrt{\left(\hat{S}^x_l\right)^2 + \left(\hat{S}^y_l\right)^2}$, which we will extensively study in the later sections.

Due to quantum and thermal fluctuations, the measurements of $\hat{S}^z_l(t)$ give different values from shot-to-shot. After the $\pi/2$ pulse of step 2, the spins are prepared in $x$ direction, so the average value yields $\langle \hat{S}^z_l(t = 0) \rangle \approx N_l/2$ and $\langle \hat{S}^z_l(t = 0) \rangle \approx 0$. In the rotating frame of Larmor frequency, the subsequent evolution does not change the expectation value of the $y$ component so that $\langle \hat{S}^y_l(t) \rangle \sim 0$ throughout. The decay of the average $\langle \hat{S}^y_l(t) \rangle$ during the evolution in step 3 tells us the strength of spin diffusion in the system. The behaviors of $\langle \hat{S}^y_l(t) \rangle$ due to spin diffusion are similar for one and three dimensions, and the difference is quantitative, rather than qualitative. On the other hand, a richer information about the dynamics of one dimensional system is contained in the noise of $\hat{S}^y_l(t)$. Such noise inherent to quantum systems is captured by higher moments $\langle (\hat{S}^y_l(t))^{n} \rangle$. In this paper, we obtain the expression for the full distribution function $P^a_l(\alpha, t)$ which can produce any moments of $\hat{S}^y_l(t)$ through the relation

$$\langle (\hat{S}^y_l(t))^{n} \rangle = \int d\alpha P^a_l(\alpha, t)\alpha^n,$$

(2)

where $P^a_l(\alpha, t) d\alpha$ represents the probability that the measurement of $\hat{S}^y_l(t)$ gives the value between $\alpha$ and $\alpha + d\alpha$. We will see in Section IV that it is also possible to obtain the joint distributions $P^{x,y}_l(\alpha, \beta, t)$ of $\hat{S}^x_l(t)$ and $\hat{S}^y_l(t)$ as well as the distribution $P^z_l(\alpha, t)$ of the squared transverse magnitude $\langle \hat{S}^z_l \rangle^2$.

Now we summarize the main results of this paper, and give a qualitative description of spin dynamics in the Ramsey sequence. Elementary excitations of spin modes in the system are described in terms of linearly dispersing spin waves with momenta $k$ and excitation energies $c_\alpha |k|$, where $c_\alpha$ is the spin wave velocity. When certain symmetry conditions are satisfied (see discussion in Section IV), spin and charge degrees of freedom decouple, and these spin waves are free and they do not interact among themselves in the low energy descriptions within so-called Tomonaga-Luttinger theory\cite{11,22}. Here, we describe the result in this decoupling limit, but the qualitative picture does not change even after the coupling between spin and charge is introduced, as we will see in Sec. V.

The initial state prepared after $\pi/2$ pulse in step 2 in which all spins point in the $x$ direction is far from the equilibrium state of the system because interactions of spins are not symmetric in terms of spin rotations. Thus, the initial state contains many excitations and the subsequent dynamics of spins is determined by time evolution
of the spin waves. A spin wave excitation with momentum $k$ rotates spins with length scale $\sim 2\pi/k$ and time scale $\sim 1/(c_s |k|)$. The amplitude of fluctuations coming from the spin wave with momentum $k$ is determined by the initial state as well as the nature of wave excitations. We find that the energy stored in each mode is approximately the same (see discussion in Sec. IV B 5), thus the amplitude of fluctuations for wave vector $k$ scales as $1/k^2$. Therefore, the fluctuation of spins is weak at short wave lengths and short times, and strong at long wave lengths and long times. In Fig. 2, we illustrate such dynamics of spins due to fluctuations of spin wave excitations. It leads to the distributions presented in Fig. 3 and Fig. 4. Here, we have plotted distribution function of the squared transverse magnitude of spins $\left( \hat{S}_x \right)^2$ (Fig. 3) and the joint distribution function (Fig. 4) with $L = 200$, $K_s = 20$ and various integration length $l/\xi_s = 20, 30, 40$. $K_s$ is the spin Luttinger parameter, which measures the strength of correlations in 1D system (see Eq. 3 below), and $\xi_s$ is a spin healing length which gives a characteristic length scale in the low energy theory of spin physics.

The multi-mode nature of one dimensional system, in which spin correlations at different length scales are destroyed in qualitatively different fashion during the dynamics, can be revealed most clearly in the squared transverse magnitude of spins $\left( \hat{S}_x \right)^2$, plotted in Fig. 3. In the initial state, all the spins are aligned in the $x$ direction, so the distribution of $\left( \hat{S}_x \right)^2$ is a delta function peak at its maximum value, $\sim (\rho)^2$, where $\rho$ is the average density of spin-up or spin-down. The evolution of spin waves lead to the fluctuations of spins and thus to the decay of the integrated magnitude of the transverse spin. How the spin waves affect the integrated magnitude of spins strongly depends on the wavelength of the excitations. Spin excitations with momenta much smaller than $\sim 2\pi/l$ do not affect $\left( \hat{S}_x \right)^2$ since these spin waves rotate the spins within $l$ as a whole, while spin excitations with higher momenta lead to the decay of the magnitude. This is in stark contrast with the $x$ component of the spin $\hat{S}_x$, which receives contributions from spin waves of all wavelengths.

As a result of different contributions of spin wave excitations with different wavelengths to the integrated spin magnitude, there are two distinct behaviors of the distribution of $\left( \hat{S}_x \right)^2$; one for short integration length $l$, which we call "spin diffusion regime" and another for long integration length $l$, which we call "spin decay regime." For short integration length $l$, the distribution function of $\left( \hat{S}_x \right)^2$ is always peaked near its maximum value $(\rho)^2$ during the dynamics because the strength of fluctuations coming from spin waves with high momenta are suppressed by $1/k^2$ (Fig. 3, $l/\xi_s = 20$). While the magnitude of spin waves does not decay in this regime, fluctuations still lead to a diffusion of $\hat{S}_x^2$, thus, we call this regime the "spin diffusion regime."

On the other hand, for long integration length, spin waves lead to fluctuations of the spins within the integration region, and the spins are randomized after a long time. This randomization of spins leads to the development of a Gaussian-like peak near $(\hat{S}_x)^2 = 0$ (Fig. 3, $l/\xi_s = 40$). During the intermediate time, both peaks at
0 and the maximum value \((\rho l)^2\) are present, and one can observe the double peak structure. Because of the strong decaying behavior of the magnitude of spin, we call this regime the "spin decay regime."

More complete behaviors of distribution functions can be captured by looking at the joint distribution functions from which we can read off the distributions of both \((S_l^\perp)^2\) and \(\hat{S}_l^x\), see Fig.4. In the "spin diffusion regime" with short \(l\), the joint distributions form a "ring" during the time evolution, whereas in the "spin decay regime" with long \(l\), they form a "disk"-like structure in the long time limit. As we will see later, a dimensionless parameter given by \(l_0 \sim \frac{\pi^2 l}{4K_s \xi_s}\) determines whether the dynamics belongs to the "spin diffusion regime" \((l_0 \leq 1)\) or the "spin decay regime" \((l_0 \gg 1)\).

We emphasize that in three dimensions, spin waves are dominated by \(k=0\) mode and therefore, there is almost no decay in the magnitude of spins throughout the dynamics. Therefore, the existence of two qualitatively different behaviors of distribution functions of \((S_l^\perp)^2\) unambiguously distinguishes the dynamics in one and three dimensions.

B. Dynamics of interference between split condensates

The dynamics of Ramsey sequence considered above can be directly mapped to the dynamics of interference pattern of split one dimensional quasi-condensate\[55\]. More specifically we consider the following sequence of operations(see Fig.5). First, we prepare one-component 1D quasi-condensate in equilibrium. At time \(t=0\), the quasi-condensate is quickly split along the axial direction, and the resulting two quasi-condensates are completely separated. The two quasi-condensates freely evolve for a hold time of \(t\), and they are released from transverse traps to observe the interference pattern between these two quasi-condensates. Such dynamics of the interference patterns as a function of hold time \(t\) has been observed in the experiment by Hofferberth et al.\[23\], where the average of interference patterns is analyzed in details. Here we study the unique one dimensional dynamics by looking at the full distributions of interference patterns (for an experimental study see: Gring et al.\[24\].)
The dynamics of split condensates can be mapped to the dynamics of the Ramsey interferometer studied in this paper. The splitting of a quasi-condensate corresponds to the initial $\pi/2$ pulse in the Ramsey sequence. If we call one of the quasi-condensates to be $L$ for left and another to be $R$ for right, $L(R)$-condensate corresponds to spin-up (spin-down) component. Thus, the density difference between the two condensates corresponds to $z$ component of the spin, namely $\hat{S}^z(r,t) = \psi^l_L(r,t) - \psi^l_R(r,t)$ where $\psi^l_i(r,t)$ is the creation operator of particles in $i = L, R(R)$ condensate. Moreover, the local phase difference between the two condensates corresponds to the local spin direction along the axial direction. Immediately after the splitting, the phases of the two condensates are the same, the interference pattern has a constructive peak at the center of two condensates, when the splitting process prepares two condensates with equal average number of particles, “phase diffusion regime” and “contrast decay regime” correspond to “phase diffusion regime” and “contrast decay regime” described in the previous section, respectively.

C. Prethermalization of one-dimensional condensates

The equilibration and relaxation dynamics of generic many-body systems are fundamental open problems. Among possible processes, it has been suggested that the time evolution of some systems prepared in non-equilibrium states results in the reaching of quasi-steady states within much shorter time than equilibration time. This quasi-steady state is often not a true equilibrium state, but rather it is a dephased state, and true equilibration takes place at much longer time scale. Yet in some cases, the physical observables in the quasi-steady states take the value corresponding to the one in thermal equilibrium at some effective temperature $T_{\text{eff}}$, displaying disguised "thermalized" states. Such surprising non-equilibrium phenomena, called prethermalization, have been predicted to occur in quantum as well as classical many-body systems and observed in Gring et al.\[24\].

In particular, integrable one dimensional systems are known not to thermalize and indeed, experiments in Ref. [27] have observed an exceedingly long equilibration time. Yet even in this extreme case, we suggest in this section that many-body one dimensional systems can reach disguised "thermalized” states through prethermalization phenomena within a short time.

Ramsey dynamics and dynamics of interference patterns between split condensates described in the previous sections are particular examples of dynamics in which slow equilibration is expected because the system essentially consists of uncoupled harmonic oscillators in the low energy description (see Sec. [IV]). In the following, we give a heuristic argument that the distribution of the interference contrast amplitudes of the two non-equilibrium quasi-condensates are given by that of two equilibrium quasi-condensates at some effective temperature $T_{\text{eff}}$. We give more details in Sec. [VI].

Long time after the splitting, the position of the interference peak becomes completely random, and yields no information. Therefore, we focus on the squared transverse magnitude of the spin $\hat{S}_r^2$. In this regime, the interference contrast is $\hat{C}^2$. In the following, we describe the physics for the dynamics of split condensates, but the same argument can be applied to Ramsey dynamics. The interference contrast of the split condensates after a long time is determined by the “average” phase fluctuations present in the system. In the dephased limit, such fluctuations are determined by the total energy present in each mode labeled by momenta $k$. Now for sufficiently fast splitting, the energy $E_{\text{split}}$ contained in each mode is independent of momenta because the density difference of quasi-condensates along the axial direction is uncorrelated in the initial state beyond the spin healing length $\xi_s$, (see discussion below Eq. (10)). On the other hand, the interference contrast of thermal condensates at temperature $T$ is determined by the thermal phase fluctua-
ions caused by excitations whose energy is distributed according to equipartition theorem; each mode in the thermal condensates contains the equal energy of $k_BT$. Thus from this argument, we find that the interference contrast of split condensates after a long time becomes indistinguishable from the one resulting from thermal condensates at temperature $k_BT_{\text{eff}} = E_{\text{split}}$. We will show in Sec [VI.C] that in fact, the full distribution function of interference contrast becomes indistinguishable for these two states. In the case of splitting two dimensional condensates, equipartition of energy and existence of "non-equilibrium temperature" was pointed out in Ref. [61].

Here we propose the occurrence of such prethermalization within Tomonaga-Luttinger theory. We emphasize that within Tomonaga-Luttinger theory of low energy excitations, different modes are decoupled and therefore no true thermalization can take place. In realistic experimental situations, such integrability can be broken and relaxation and thermalization processes are expected to occur after a long time dynamics. The requirement to observe the prethermalization phenomena predicted in this theory in experiments depends on the time-scale of other possible thermalization processes we did not consider in our model such as the effective three-body collisions[62, 63], relaxation of high energy quasiparticles[64], or interactions among the collective modes through anharmonic terms we neglected in Tomonaga-Luttinger theory[65]. When all these processes occur at much slower time scale than the prethermalization timescale, which is roughly given by the integration length divided by the spin sound velocity $\sim 1/c_s$, for decoupling case, the observation of prethermalization should be possible. In one dimension, the dynamics is strongly constrained due to the conservation of energy and momentum, and therefore is likely that the dynamics is dominated by the modes described by Tomonaga-Luttinger theory for long time for quasi-condensates with low initial temperatures.

Such prethermalizations are expected to occur even in higher dimensional systems[19, 25, 61, 63]. We note that the conditions for the experimental observations of the phenomena might be more stringent because true thermalization processes are expected to take place much more quickly in two and three dimensional systems.

**III. TWO COMPONENT BOSE MIXTURES IN ONE DIMENSION: HAMILTONIAN**

In this paper, we study the dynamics of two-component Bose mixtures in one dimension through Tomonaga-Luttinger formalism[21, 22]. As we have stated before, we assume the rotating frame, in which spin-up and spin-down particles have the same chemical potential in the absence of interactions. The Hamiltonian of two component Bose mixtures in one dimension is given by

$$H = \int_{-L/2}^{L/2} dr \left[ \sum_i \frac{1}{2m_i} \nabla \psi_i^\dagger (r) \nabla \psi_i (r) + \sum_{ij} g_{ij} \psi_i^\dagger (r) \psi_j^\dagger (r) \psi_j (r) \psi_i (r) \right]$$

where $\psi_i$ with $i = \uparrow, \downarrow$ describe two atomic species with masses $m_i$ and $g_{ij}$ are the interaction strengths given by $g_{ij} = \nu_{\perp} \delta_{ij}$ where $\nu_{\perp}$ is the frequency of transverse confinement potential and $\delta_{ij}$ are the scattering lengths between spin $i$ and $j$. System size is taken to be $L$, and we take the periodic boundary condition throughout the paper. In addition, we use the units in which $\hbar = 1$.

In the low energy description, the Hamiltonians for weakly interacting bosons after the initial $\pi/2$ rotation can be written in quadratic form, and given by

$$H = H_\uparrow + H_\downarrow + H_{\text{int}},$$

$$H_\uparrow = \int_{-L/2}^{L/2} dr \left[ \frac{\rho}{2m_\uparrow} (\nabla \phi_\uparrow (r))^2 + g_\uparrow \bar{\phi}_\uparrow (\delta_{\uparrow})^2 \right],$$

$$H_\downarrow = \int_{-L/2}^{L/2} dr \left[ \frac{\rho}{2m_\downarrow} (\nabla \phi_\downarrow (r))^2 + g_\downarrow \bar{\phi}_\downarrow (\delta_{\downarrow})^2 \right],$$

$$H_{\text{int}} = 2 \int_{-L/2}^{L/2} dr (r) \left[ g_\uparrow \bar{\phi}_\uparrow \delta_{\uparrow} (r) + g_\downarrow \bar{\phi}_\downarrow \delta_{\downarrow} \nabla \phi_\uparrow \nabla \phi_\downarrow (r) \right],$$

where $\rho$ is the average density of each species and $\delta_{\sigma}$ are variables representing the phase and density fluctuation for the particle with spin $\sigma$. These variables obey a canonical commutation relation $[\delta_{\sigma} (r), \bar{\phi}_\sigma (r')] = -i \delta (r - r')$. In the Hamiltonian above, we included the kinetic interaction term $g_\sigma^2 \delta_{\sigma}$, which is zero for weakly interacting bosons, but allowed by inversion symmetry and non-zero for generic Tomonaga-Luttinger Hamiltonians.

We note that in the weakly interacting case, one can obtain the parameters of the Hamiltonian in Eq. (4) such as $g_\sigma$ and $m_i$ through hydrodynamic linearization of the microscopic Hamiltonian. In this case, we assume the small fluctuations of the densities $\delta_{\sigma}$ and phases $\nabla \phi_\sigma$ and expand the Hamiltonian in Eq. (3) to the second order in these variables through the expression $\psi_\sigma^\dagger \sim \sqrt{\rho + \delta_{\sigma}} e^{i \hat{\phi}_\sigma}$, resulting in the form of the Hamiltonian in Eq. (1). Due to this assumptions of small spatial variations of the phase, $\hat{\phi}_\sigma$ and $\bar{\phi}_\sigma$ represent the "coarse-grained" variables where collective modes have linear dispersions. The Hamiltonian of Tomonaga-Luttinger theory in Eq. (4) can also describe effective low-energy physics of strongly interacting systems, but in this case there is no simple relation between microscopic parameters and the parameters of the Hamiltonian in Eq. (1).

In order to describe the spin dynamics, we define spin and charge operators as the difference and the sum of spin up and down operators, i.e. $\phi_\uparrow = \phi_\uparrow - \phi_\downarrow$, $\phi_\downarrow = \phi_\uparrow + \phi_\downarrow$, $\bar{\phi}_\uparrow = \frac{1}{2}(\bar{\phi}_\uparrow - \bar{\phi}_\downarrow)$, $\bar{\phi}_\downarrow = \frac{1}{2}(\bar{\phi}_\uparrow + \bar{\phi}_\downarrow)$. In this representation,
the Hamiltonian in Eq. (4) becomes

\[
H = H_s + H_c + H_{\text{mix}}
\]

\[
H_s = \int_{-L/2}^{L/2} dr \left[ \frac{\rho}{2n_s} (\nabla \phi_s(r))^2 + g_s (\hat{n}_s(r))^2 \right]
\]

\[
H_c = \int_{-L/2}^{L/2} dr \left[ \frac{\rho}{2n_c} (\nabla \phi_c(r))^2 + g_c (\hat{n}_c(r))^2 \right]
\]

\[
H_{\text{mix}} = 2 \int_{-L/2}^{L/2} dr \left[ g_{\text{mix}} \hat{n}_s(r)\hat{n}_c(r) + g_{\text{mix}}^\phi \nabla \phi_s(r) \nabla \phi_c(r) \right]
\]

where interaction strengths are given by \( g_c = g_{\uparrow\uparrow} + g_{\downarrow\downarrow} + 2g_{\uparrow\downarrow} \), \( g_s = g_{\uparrow\uparrow} + g_{\downarrow\downarrow} - 2g_{\uparrow\downarrow} \), \( g_{\text{mix}} = g_{\uparrow\uparrow} - g_{\downarrow\downarrow} \), \( g_{\text{mix}}^\phi = \rho/(8m_s) - \rho/(8m_c) \). The masses are given by the relations \( \rho/(2m_c) = \rho/(8m_1) + \rho/(8m_1) + g_{\uparrow\uparrow}/2 \) and \( \rho/(2m_s) = \rho/(8m_1) - \rho/(8m_1) - g_{\downarrow\downarrow}/2 \).

The spin variables \( \phi_s \) and \( \hat{n}_s \) are "coarse-grained" in the sense that they represent the operators in the long wavelength beyond the spin healing length \( \xi_s \). \( \xi_s \) is determined from microscopic physics and gives the length below which the kinetic energy of spins wins over the interaction energy, see Eq. (5) above. For weakly interacting bosons with \( m_1 = m_2 = m \), it is given by \( \xi_s = \pi/\sqrt{mg} \). In the following, we assume that the number of particles within the spin healing length is large, i.e. \( \xi_s \gg 1 \). This condition is always satisfied for weakly interacting bosons.

In the next section, we consider the case \( g_{\text{mix}} = 0 \) and \( g_{\text{mix}}^\phi = 0 \), in which spin and charge degree of freedom decouple. Then the dynamics of spins is completely described by the spin Hamiltonian in Eq. (6). The general case in which \( g_{\text{mix}} \neq 0 \) and \( g_{\text{mix}}^\phi \neq 0 \) will be treated in Sec. V.

IV. DYNAMICS OF FULL DISTRIBUTION FUNCTION FOR DECOUPED SPIN AND CHARGE DEGREES OF FREEDOM

A. Hamiltonian and initial state

The experiment of Widera et al. [22] used \( F = 1, m_F = +1 \) and \( F = 2, m_F = -1 \) states of \(^{87}\)Rb for spin-up and spin-down particles, respectively. These hyperfine states have the scattering lengths \( a_{\sigma\sigma} \) such that \( a_{\uparrow\uparrow} \approx a_{\downarrow\downarrow} \). Consequently, the mixing Hamiltonian in Eq. (7) approximately vanishes for weak interactions. Motivated by this experiment, here we consider the decoupling of spin and charge degrees of freedom [52]. Spin dynamics in this case is completely determined by the spin Hamiltonian

\[
H_s = \frac{c_s}{2} \int \left[ \frac{K_s}{\pi} (\nabla \phi_s(r))^2 + \frac{\pi}{K_s} \hat{n}_s^2(r) \right] dr
\]

where \( K_s \) is the spin Luttinger parameter representing the strength of interactions, and \( c_s \) is spin sound velocity.

\( K_s \) and \( c_s \) are directly related to the spin healing length \( \xi_s \) in the weak interaction limit, given by \( 2K_s = \rho_s \) and \( c_s = 2\pi/\xi_s \). \( \hat{n}_s(r,t) \) is the local spin imbalance

\[
\hat{n}_s = \psi_s^\dagger (\frac{1}{2} \sigma^\phi_{\alpha\beta} \psi_{\beta}) + \phi_s(r,t) \text{ is related to the direction of the transverse spin component } \rho_{\alpha\beta} \sigma^\phi_{\alpha\beta} \psi_{\beta}.
\]

Here, \( \psi_s^\dagger \) is the creation operator of spin \( \alpha = \uparrow, \downarrow \). These variables \( \hat{n}_s \) and \( \phi_s \) obey a canonical commutation relation \( [\hat{n}_s(r), \phi_s(r')] = -i\hbar (r - r') \).

Other spin variables can be similarly defined in terms of coarse grained spin variables \( \hat{n}_s \) and \( \phi_s \). In the following, we consider the general transverse spins pointing in the direction \( (x,y,z) = (\cos \theta, \sin \theta, 0) \) integrated over \( l \) given by

\[
\mathcal{S}_l^\theta = \int_{-l/2}^{l/2} dr \psi_s^\dagger (r,t) \left( \cos \theta \sigma^\phi_{\alpha\beta} + \sin \theta \sigma^\phi_{\alpha\beta} \right) \psi_s(r,t)
\]

\[
= \int_{-l/2}^{l/2} dr \frac{l}{2} (e^{i\phi_s(r) - \theta} + e^{-i\phi_s(r) - \theta})
\]

where \( \sigma^\phi \) with \( \alpha = x, y \) are Pauli matrices. Here \( \mathcal{S}_l^\theta \) with \( \theta = 0 \) corresponds to spin \( x \) operator and \( \theta = \pi/2 \) corresponds to spin \( y \) operator. In order to explore the one dimensional dynamics resulting from Hamiltonian in Eq. (8), we analytically compute the \( n \)-th moment of the spin operator \( \mathcal{S}_l^n \), \( \langle \mathcal{S}_l^n \rangle \), after time \( t \) of the \( \pi/2 \) pulse of the Ramsey sequence. Then, the full distribution functions of \( \mathcal{S}_l^n \) and \( \mathcal{S}_l^\theta \), as well as the joint distribution of these will be obtained from \( \langle \mathcal{S}_l^n \rangle \).

In order to study the dynamics of Ramsey interferometer in terms of low energy variables \( \hat{n}_s \) and \( \phi_s \), we need to write down an appropriate state after the \( \pi/2 \) pulse in terms of \( \hat{n}_s \) and \( \phi_s \). If pulse is sufficiently strong, each spin is independently rotated into \( x \) direction after the \( \pi/2 \) pulse. Naively, this prepares the initial state in the eigenstate of \( \mathcal{S}_l^x \) with \( \phi_s(r) \) as eigenvalue \( \phi_s(r) = 0 \). However, due to the commutation relation between \( \hat{n}_s \) and \( \phi_s \), such an initial state has an infinite fluctuation in \( \hat{n}_s \) and therefore, the state has an infinite energy according to Eq. (8). This unphysical consequence comes about because the low energy theory in Eq. (8) should not be applied to the physics of short time scale given by \( 1/E_c \) where \( E_c \) is the high energy cutoff of Tomonaga-Luttinger theory. During this short time dynamics, the initial state establishes the correlation at the length scale of spin healing length \( \xi_s \). The state after this short time dynamics can now be described in terms of the coarse-grained variables \( \hat{n}_s(r) \) and \( \phi_s(r) \). The variables \( \hat{n}_s(r) \) and \( \phi_s(r) \) are defined on the length scale larger than the spin healing length \( \xi_s \). Since the \( z \) component of spins are still uncorrelated after \( \xi_s \) after the initial short time dynamics, the appropriate initial condition of the state is written as

\[
\langle S^z(r)S^z(r') \rangle = \langle \hat{n}_s(r)\hat{n}_s(r') \rangle = \frac{\rho_{\uparrow\uparrow}}{2}(r - r')
\]
where the delta function $\delta(r - r')$ should be understood as a smeared delta function over the scale of $\xi_s$. Because the state after the short time dynamics is still close to the eigenstate of the $\hat{S}^z(r)$ operator, spins are equal superpositions of spin-up and spin-down. Then the distribution of $\hat{S}_l^z = \int_0^L \hat{S}^z(r) dr$ is determined through random picking of the values $\pm 1/2$ for $2\rho_l$ particles. Due to the central limit theorem, the distribution of $\hat{S}_l^z = \int_0^L \hat{S}^z(r) dr$ is Gaussian, i.e. $\langle (\hat{S}_l^z)^2 \rangle = (2n_l^/) (\rho_l \eta / 2)^n$. In particular, $\langle (\hat{S}_l^z)^2 \rangle = \rho_l \eta / 2$, which determines the magnitude of the fluctuation for $\hat{S}^z(r)$ in Eq.[10]. In Eq.[10], we also introduced the phenomenological parameter $\eta$ which accounts for the decrease and increase of fluctuations coming from, for example, imperfections of $\pi / 2$ pulse. The ideal, fast application of $\pi / 2$ pulse corresponds to $\eta = 1$. In the experimental realization of Ref. [22], $\eta$ was determined to be between 0.8 and 1.3 through the fitting of the experiment with Tonomaga-Luttinger theory for the time evolution of the average $x$ component of the spin, $\langle \hat{S}_l^x \rangle$. Through engineering of the initial state such as the application of a weak $\pi / 2$ pulse, $\eta$ can also be made intentionally smaller than 1.

A convenient basis to describe the initial state of the dynamics above is the basis that diagonalizes the spin Hamiltonian of Eq.[8]. The phase and density of the spins $\hat{\phi}_s(r)$ and $\hat{n}_s(r)$ can be written in terms of the creation $\hat{b}^\dagger_{s,k}$ and annihilation $\hat{b}_{s,k}$ operators of elementary excitations for the spin Hamiltonian in Eq.[8] as

$$
\hat{\phi}_s(r) = \frac{1}{\sqrt{L}} \sum_k \hat{\phi}_{s,k} e^{ikr} = \frac{1}{\sqrt{L}} \left( \sum_{k \neq 0} -i \sqrt{\pi \over 2|k|/K_s} (\hat{b}^\dagger_{s,k} - \hat{b}_{s,-k}) e^{ikr} + \hat{\phi}_s(0) \right)
$$

$$
\hat{n}_s(r) = \frac{1}{\sqrt{L}} \sum_k \hat{n}_{s,k} e^{ikr} = \frac{1}{\sqrt{L}} \left( \sum_{k \neq 0} \sqrt{|k|/K_s} (\hat{b}^\dagger_{s,k} + \hat{b}_{s,-k}) e^{ikr} + \hat{n}_s(0) \right)
$$

$$
\mathcal{H}_s = \sum_{k \neq 0} c_s |k| \hat{b}^\dagger_{s,k} \hat{b}_{s,k} + \frac{\pi c_s}{2K_s} \hat{n}_{s,0}^2
$$

where we defined $\hat{\phi}_{s,k}$ and $\hat{n}_{s,k}$ to be the Fourier transform of operators $\hat{\phi}_s(r)$ and $\hat{n}_s(r)$. $\hat{b}^\dagger_{s,k}$ creates a collective mode with momentum $k$ and follows a canonical commutation relation $[\hat{b}_{s,k}, \hat{b}^\dagger_{s,k}] = 1$. Note that $k = 0$ mode has no kinetic energy, and it naturally has different evolution from $k \neq 0$ modes.

The Gaussian state determined by Eq.[10] takes the form of a squeezed state of operators $\hat{b}_{s,k}$, and it is given by

$$
|\psi_0\rangle = \frac{1}{\sqrt{N}} \exp \left( \sum_{k \neq 0} W_k \hat{b}^\dagger_{s,k} \hat{b}^\dagger_{s,-k} \right) |0\rangle |\psi_{s,k=0}\rangle
$$

$$
\langle n_s,0 | \psi_{s,k=0} \rangle = \exp \left( -\frac{1}{2\rho_l} n_{s,0}^2 \right)
$$

where $2W_k = \frac{1}{\sqrt{\pi} \alpha_k}, \alpha_k = |k|/\pi \eta |n_s,0|$. Here the state $|n_s,0\rangle$ is the normalized eigenstate of the operator $\hat{n}_{s,0}$ with eigenvalue $n_{s,0}$. The summation of $k$ in the exponent has a ultraviolet cutoff around $k_c = 2\pi / \xi_s$. $N$ is the overall normalization of the state. It is easy to check that $\langle \hat{n}_{s,k} \hat{n}_{s,k'} | \psi_0 \rangle = \frac{\rho_l}{2} \delta_{k,-k'}$, which corresponds to Eq. [10].

B. Moments and full distribution functions of spins

After free evolution of the initial state $|\psi_0\rangle$ for time $t$, the state becomes $|\psi(t)\rangle = e^{-iH_s t} |\psi_0\rangle$. We characterize the state at time $t$ by the nth moments of spin operators $\langle (\hat{S}^r)^n \rangle$. As we will see below, the full distribution function can be constructed from the expression of $\langle (\hat{S}^r)^n \rangle$ [18].

We consider the evaluation of moments $\langle (\hat{S}^r)^n \rangle$ at time $t$, $|\psi(t)\rangle$. Each momentum $k$ component of the initial state $|\psi_0\rangle$ independently evolves in time. Since $k = 0$ mode has a distinct evolution from other $k \neq 0$ modes, we separately consider $k = 0$ and $k \neq 0$ modes.

1. $k = 0$ mode

The Hamiltonian of $k = 0$ mode is given by $H_{s,k=0} = \frac{\pi c_s}{2K_s} n_{s,0}^2$ in Eq.[11]. Therefore, in the basis of $n_{s,0}$, $k = 0$ part of the state $|\psi(t)\rangle$ is given by

$$
\langle n_{s,0} | e^{-iH_{s,k=0} t} | n_{s,0} \rangle = \frac{1}{N_{n=0}} \exp \left\{ -\frac{1}{2\rho_l} \frac{(n_{s,0} - \pi \eta t / 2\xi_s) n_{s,0}^2}{2K_s} \right\}
$$

where $N_{n=0}$ is the normalization of the state. The initial Gaussian state of $n_{s,0}$ stays Gaussian at all times, and any analytic operator of $\hat{\phi}_{s,0}$ and $\hat{n}_{s,0}$ can be exactly evaluated through Wick’s theorem. For example, $k = 0$ part contributes to the decay of the average of the $x$ component of spin $\langle \hat{S}_l^x \rangle_{k=0} = \rho_l \text{Re} \left( e^{i\hat{\phi}_{s,0}} / \sqrt{N} \right)$ as

$$
\langle \hat{S}_l^x \rangle_{k=0} = \rho_l e^{-\frac{\pi c_s \pi t}{K_s}}
$$

$$
\langle \hat{\phi}_{s,0}^2 \rangle_t = \frac{1}{2\rho_l} + \left( c_s \pi t / K_s \right)^2 \frac{\eta \rho_l}{2}
$$

This diffusion of the spin from $k = 0$ contribution is generally present in any dimensional systems, and not particular to one dimension. Physical origin of this diffusion
is the interaction dependent on the total spin, $\hat{S}_z$. The eigenstate of $\hat{S}_z$ with eigenvalue $pl$ is the superposition of different eigenstates of $\hat{S}_z$ with eigenvalues $m_z$, and they accumulate different phases $e^{-im_zl}$ in time. This leads to the decay of $\langle \hat{S}_z \rangle$. In the thermodynamic limit $L \to \infty$, the uncertainty of $\hat{S}_z$ becomes diminishingly small, and therefore, the decay of $\langle \hat{S}_z \rangle$ coming from $k = 0$ goes to zero. More interesting physics peculiar to one-dimensional systems comes from $k \neq 0$ modes. In the case of three dimensional systems, macroscopic occupancy of a single particle state is absent in one dimension, so $k \neq 0$ momentum excitations have much more significant effect in one dimensional dynamics.

2. $k \neq 0$ contribution

The exact evaluation of spin moments $\langle (\hat{S}_z)^m \rangle$ for $k \neq 0$ is possible through the following trick. Consider the annihilation operator $\hat{\phi}_{s,k}(t)$ for the state $|\psi(t)\rangle$ such that $\gamma_{s,k}(t)|\psi(t)\rangle = 0$. If we write the operators $\hat{\phi}_{s}(r)$ in terms of $\gamma_{s,k}(t)$ and $\gamma_{s,k}^\dagger(t)$, then $k \neq 0$ part of the $m$th moment schematically takes the form $\langle (\hat{S}_z)^m \rangle \sim \langle e^{i\sum_{k \neq 0} C_{s,k} \gamma_{s,k} + C_{s,k}^* \gamma_{s,k}^\dagger} \rangle$ (Here and in the following, we drop the time dependence of $\gamma_{s,k}$ from the notation). Using the property $e^{\gamma_{s,k}^\dagger} |\psi(t)\rangle = (1 + \gamma_{s,k} + \cdots) |\psi(t)\rangle = |\psi(t)\rangle$ and the identity $e^{A+B} = e^{A}e^{B}e^{-\frac{1}{2}[A,B]}$ where $[A,B]$ is a c-number, we can evaluate $m$th moments as $\langle (\hat{S}_z)^m \rangle \sim \langle e^{C_{s,k} \gamma_{s,k}^\dagger e^{-\frac{1}{2} \sum_{k \neq 0} [C_{s,k},C_{s,k}^*] e^{iC_{s,k} \gamma_{s,k}}} e^{iC_{s,k} \gamma_{s,k}} \rangle$

$$= \exp\left(-\frac{1}{2} \sum_{k \neq 0} |C_{s,k}|^2 \right).$$

It is straightforward to check that $\gamma_{s,k}$ operator is given by the linear combination of $b_{s,k}$ and $b_{s,k}^\dagger$ as follows,

$$\begin{pmatrix}
\gamma_{s,-k}^\dagger(t) \\
\gamma_{s,k}(t)
\end{pmatrix} = \begin{pmatrix}
\sqrt{1-4|W_{s}^2|} & -2W_{s}e^{-i\theta_{s,k}} \\
-2W_{s}e^{i\theta_{s,k}} & \sqrt{1-4|W_{s}^2|}
\end{pmatrix} \begin{pmatrix}
b_{s,-k}^\dagger \\
b_{s,k}
\end{pmatrix}. \tag{15}
$$

$\gamma_{s,k}$ and $\gamma_{s,k}^\dagger$ obey a canonical commutation relation $[\gamma_{s,k}, \gamma_{s,k}^\dagger] = 1$. In terms of these $\gamma_{s,k}$, the expression of $\hat{\phi}_{s,k}(t)$ becomes

$$\frac{1}{\sqrt{L}} \hat{\phi}_{s,k} = C_{s,k} \gamma_{s,k}^\dagger + C_{s,k}^* \gamma_{s,-k},$$

$$C_{s,k} = -i \sqrt{\frac{\pi}{2|k| L}} e^{i|\omega_{s,k}|t} - 2W_{s}e^{-i\omega_{s,k}|t|} \sqrt{1-4|W_{s}^2|}. \tag{16}
$$

$C_{s,k}(t)$ measures the fluctuation, or variance, of phase in the $k$th mode at time $t$, given by $\langle \hat{\phi}_{s,k}(t)^2 \rangle = \langle \hat{\phi}_{s,k}(t) \hat{\phi}_{s,-k}(t) \rangle$. Indeed, since $\gamma_{s,k}$ is the annihilation operator of our state at time $t$, we immediately conclude that $\langle \hat{\phi}_{s,k}(t)^2 \rangle / L = |C_{s,k}(t)|^2$.

Using the technique described above, $m$th moment of $\hat{S}_z^0$ becomes (we include both $k = 0$ and $k \neq 0$ contributions in the expression below)

$$\langle \psi(t) \rangle \left( \int \frac{d^{1/2}}{\sqrt{L}} S_z^0(r) dr \right)^m |\psi(t)\rangle = \prod_{i=1}^{m} \left( \int \frac{d^{1/2}}{\sqrt{L}} S_z^0(r_i) dr \right) \sum_{s_i = \pm 1} \exp \left( -\frac{1}{2} \sum_{k} \xi_{s,k} \right) \langle \langle s_i \rangle \rangle \left( \xi_{s_i} \right)^2 \times e^{-i(\sum_{s_1})^\theta}
$$

where $\xi_{s,k} = \sqrt{\frac{\gamma_{s,k}(t)^2}{L}} (s_1 e^{ikr_1} + \cdots + s_m e^{ikr_m})$. $s_i$ takes either the value 1 or $-1$, and $\sum_{s_1}$ sums over all possible set of values. Note that $L$ is the total system size and $l$ is the integration range.

3. Full Distribution Function

Calculation of the full distribution functions from moments in Eq. (17) is studied by the techniques introduced in Ref. [18] through mapping to the statistics of random surfaces. In this subsection, we provide the details of the calculation.

Eq. (17) is simplified if the integrations for each $r_i$ can be independently carried out. This is not possible in Eq. (17) because $e^{ikr}$ and $e^{ikr_j}$ for $i \neq j$ are coupled in $\langle s_i \rangle^2$ = $\langle \text{Re} \xi_{s_i} \rangle^2 + \langle \text{Im} \xi_{s_i} \rangle^2$. To untangle this, we introduce Hubbard-Stratonovich transformation, $e^{-\frac{\pi}{4}} = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{-\frac{x^2}{4}} e^{ixl}$, for example,

$$e^{-\frac{1}{2} \text{Re} \xi_{s_i}^2} = \int_{-\infty}^{\infty} \frac{d\lambda_{s_i}}{2\pi} e^{-\lambda_{s_i}^2/2} e^{i\lambda_{s_i} \text{Re} \xi_{s_i}^2} \text{Im} \xi_{s_i}.$$
\[
\langle \psi(t) \rangle \left( \int_{-l/2}^{l/2} S^\theta(r)dr \right)^m \left| \psi(t) \right> = \sum_{\{s_i\}} \prod_{k} \int_{-\infty}^{\infty} e^{-\left(\lambda^2_{sk} + \lambda^2_{sk}\right)/2} \frac{d\lambda_{sk} d\lambda_{sk}}{\sqrt{2\pi} \sqrt{2\pi}} \left( \frac{m}{1} \right) \left( \int_{-l/2}^{l/2} pdr \right) \frac{\sqrt{2\pi}}{2}
\]

where we introduced \( \xi_{sk}^{(ri)} = \sqrt{\frac{\left|\phi_{sk}(r)^2\right|}{L}} e^{ikr} \). Summation over \( s_i = \pm 1 \) can now be carried out. Furthermore, we introduce new variables \( \lambda_{rsk} \) and \( \lambda_{sk} \), and replace \( \lambda_{sk} \) and \( \lambda_{rsk} \) through the relation \( \lambda_{sk} = \sqrt{\lambda^2_{rsk} + \lambda^2_{sk}} \) and \( \cos(\lambda_{sk}) = \lambda_{rsk}/\sqrt{\lambda^2_{rsk} + \lambda^2_{sk}} \). These operations result in the simplified expression,

\[
\langle \psi(t) \rangle \left( \int_{-l/2}^{l/2} S^\theta(r)dr \right)^m \left| \psi(t) \right> = \prod_{k, a = r, \theta} \frac{1}{2\pi} \int d\lambda_{sk} \times \lambda_{rsk} e^{-\lambda^2_{sk}/2} \left( \rho \int_{-l/2}^{l/2} dr \cos \left[ \chi(r, \{\lambda_{jsk}\}) - \theta \right] \right)^m,
\]

\[\text{(18)}\]

where

\[
\chi(r, \{\lambda_{jsk}\}) = \sum_k \sqrt{\frac{|\phi_{sk}(r)^2|}{L}} \lambda_{rsk} \sin(kr + \theta_{sk}), \quad \text{(19)}
\]

\[
\langle \phi_{sk}(r)^2 \rangle = \frac{\pi}{2|k| K_s} \sin^2(c_s k|t|) + \frac{\alpha^2}{\alpha_k} \cos^2(c_s k|t|) (k \neq 0), \quad \text{(20)}
\]

\[
\langle \phi_{sk}(r)^2 \rangle = \frac{1}{2|k|} + \left( \frac{c_s \pi t}{K_s} \right)^2 \left( \frac{\eta}{2} \right) \quad (k = 0),
\]

with \( \alpha_k = \frac{|k| K_s}{\pi \eta} \). The integration over \( \lambda_{rsk} \) and \( \lambda_{sk} \) in Eq. (18) extends from 0 to \( \infty \) and from \( -\pi \) to \( \pi \), respectively.

Comparing the expression in Eq. (18) and the implicit definition of a distribution function in Eq. (2), it is easy to identify the distribution function as

\[
P^\theta(\alpha) = \prod_k \int_{-\pi}^{\pi} \frac{d\lambda_{sk}}{2\pi} \int_0^\infty \lambda_{rsk} e^{-\lambda^2_{sk}/2} d\lambda_{sk}
\]

\[
\times \delta \left( \alpha - \rho \int_{-l/2}^{l/2} dr \cos \left[ \chi(r, \{\lambda_{jsk}\}) - \theta \right] \right).
\]

\[\text{(21)}\]

This function can be numerically evaluated through Monte Carlo method with weight \( \lambda_{rsk} e^{-\lambda^2_{sk}/2} \) for \( \lambda_{rsk} \) and equal unity weight for \( \lambda_{sk} \).

While we have assumed that the chemical potentials of spin-up and spin-down atoms are the same in the absence of interactions by going to the rotating frame, it is easy to obtain the expression for distribution functions in the lab frame. The energy difference \( E \) between spin-up and spin-down atoms results in the rotation of the spin in the \( x - y \) plane at a constant angular velocity \( E \). Therefore, the distribution in the lab frame is obtained by replacing \( \theta \rightarrow \theta + Et \) in Eq. (21).

In this section, we have focused on the distribution function of spins in \( x - y \) plane, but it is also possible to obtain the distribution function of \( z \) component of the spin, and we present the result in the Appendix A2.

4. Joint Distribution Function

From the expression for the spin operators in Eq. (9), we observe that the spin operators for the \( x \) and \( y \) directions commute in the low energy description. This is because spin operators in Tomonaga-Luttinger theory are coarse-grained over \( \sim \rho \xi \) particles, and since for weak interactions \( \rho \xi \gg 1 \), the uncertainty of measurements coming from non-commutativity of \( \tilde{S}^x \) and \( \tilde{S}^y \) becomes suppressed. The possibility of simultaneous measurements of \( x \) and \( y \) gives the values between \( \alpha \) and \( \alpha + da \), and \( \beta \) and \( \beta + db \), respectively. Here we provide the expression for \( P^{xy}(\alpha, \beta) \) and proves that this is indeed the unique solution.

The joint distribution function \( P^{xy}(\alpha, \beta) \) is given by the following expression

\[
P^{xy}(\alpha, \beta) = \prod_k \int_{-\pi}^{\pi} \frac{d\lambda_{sk}}{2\pi} \int_0^\infty \lambda_{rsk} e^{-\lambda^2_{sk}/2} d\lambda_{sk}
\]

\[
\times \delta \left( \alpha - \rho \int_{-l/2}^{l/2} dr e^{i\chi(r,\{\lambda_{jsk}\})} \right).
\]

\[\text{(22)}\]

where the expression for \( \chi(r, \{\lambda_{jsk}\}) \) is given in Eq. (19).

To prove it, we first show that Eq. (22) reproduces the distribution function \( P^\theta(\gamma) \) in Eq. (21) for all \( \theta \). Then, we show that a function with this property is unique, and therefore the expression in Eq. (21) is necessarily the joint distribution function.

Given a joint distribution function \( P^{xy}(\alpha, \beta) \), we can determine the distribution function \( P^\theta(\gamma) \) of a spin pointing in the direction \( (\cos \theta, \sin \theta, 0) \). Consider the spin \( \vec{S} \) in the \( x - y \) plane with \( \vec{S} = (\alpha, \beta, 0) \) whose probability distribution is given by \( P^{xy}(\alpha, \beta) \). The projection of the spin...
we see that
Now, if we plug in the expression of Eq. (22) in Eq. (23),

sides of Eq. (24) in terms of \( \gamma \),
i.e. above property,
for all \( \gamma \), we have the equality
\( Q\gamma \) show that
define \( Q\gamma \) function with the

Now we prove the uniqueness of a function with the
above property, i.e. a function that reproduces Eq. (21)
through the relation Eq. (23). Suppose you have another
distribution \( P_{t}^{x,y}(\alpha, \beta) \) that satisfies Eq. (23) for all \( \theta \). We
define \( Q(\alpha, \beta) = P_{t}^{x,y}(\alpha, \beta) - P_{t}^{x,y}(\alpha, \beta) \). Our goal is to
show that \( Q(\alpha, \beta) \) must be equal to zero. By definition, we have the equality

\[
0 = \int d\gamma d\beta Q(\alpha, \beta) \delta(\gamma - \alpha \cos \theta - \beta \sin \theta),
\]

for all \( \theta \) and \( \gamma \). If we take the Fourier transform of both
sides of Eq. (24) in terms of \( \gamma \), we obtain

\[
0 = \int d\gamma \int d\beta Q(\alpha, \beta) \delta(\gamma - \alpha \cos \theta - \beta \sin \theta) e^{i\omega \gamma}
= \int d\alpha Q(\alpha) e^{i\tilde{w} \cdot \tilde{\alpha}},
\]

In the last line, we defined \( \tilde{w} = w(\cos \theta, \sin \theta) \) and \( \tilde{\alpha} = (\alpha, \beta) \). Notice that this equation holds for any \( \tilde{w} \). Then
this last expression is just like (two-dimensional) Fourier
transform of \( Q \). By taking the inverse fourier transform of
the last expression in terms of \( \tilde{w} \), we find

\[
0 = \int_{-\infty}^{\infty} d\tilde{w} \int d\alpha Q(\alpha) e^{i\tilde{w} \cdot (\tilde{\alpha} - \tilde{\alpha})} Q(\tilde{\alpha}),
\]

thereby proving the uniqueness of the joint distribution
\( P_{t}^{x,y}(\alpha, \beta) \).

From the joint distribution function in Eq. (22), one can also obtain other distributions, such as the distribution
\( P_{t}^{L}(\gamma) \) of the square of the transverse spin magnitude,
\( (S_{z}^{t}(t))^{2} \), which is given by

\[
P_{t}^{L}(\gamma) = \int_{-\infty}^{\infty} d\alpha d\beta P_{t}^{x,y}(\alpha, \beta) \delta(\gamma - \alpha^{2} - \beta^{2})
= \int_{-\pi}^{\pi} d\lambda_{rsk} \int_{0}^{\infty} \lambda_{rsk} e^{-x_{rsk} \lambda_{rsk} / 2} d\lambda_{rsk}
\times \delta \left( \gamma - \rho \int_{-\pi/2}^{\pi/2} d\chi e^{i\chi(r_{(l)} \lambda_{rsk})} \right)^{2}
\]

\[
(25)
\]

5. Interpretation of the distribution dynamics

The form of the distribution function in Eq. (22)
encapsulates the interpretation in terms of dynamics
originating from spin waves explained in Sec II. Here
\( e^{i\chi(r_{(l)} \lambda_{rsk})} \) represents the spin direction at coordinate \( r \),
where the x–y plane of the spin component is taken
to be a complex plane. Then Eq. (22) suggests that for
a given instance of the set \( \{ \lambda_{rsk}, S_{z}^{t} \} \) is simply
the sum of the local spin directions \( e^{i\chi(r_{(l)} \lambda_{rsk})} \) over
the integration length \( l \). The local spin direction at
position \( r \) are determined by the phase \( \chi(r_{(l)} \lambda_{rsk}) \), which
receives contributions from each spin wave of momentum
\( k \) with strength \( A_{k}(t) = \lambda_{rsk} \sqrt{\langle \hat{\phi}_{s,k}(t) \rangle^{2}} \). Spin waves
with momenta \( k \) rotate the spins as \( \sin(kr + \lambda_{rsk}) \) (see
the expression of \( \chi(r_{(l)} \lambda_{rsk}) \) in Eq. (19)). The rotation
strength \( A_{k}(t) \propto \lambda_{rsk} \) has the distribution \( \lambda_{rsk} e^{-x_{rsk} \lambda_{rsk} / 2} \),
which represents the quantum fluctuation of the spins.
On the other hand, \( \lambda_{rsk} \) is distributed uniformly between
\( -\pi \) and \( \pi \).

The dynamics of phase fluctuations \( \langle \hat{\phi}_{s,k}(t) \rangle^{2} \) can
in fact be easily understood by considering the Hamiltonian
given by Eq. (8) as a harmonic oscillator for each
\( k \) (Fig. 6). We first note that the initial state has a
large fluctuation of density \( \hat{n}_{s,k} \) because the initial \( \pi/2 \)
pulse prepares the state in the (almost) eigenstate of

\( \hat{S} \) onto the axis pointing in the direction \((\cos \theta, \sin \theta, 0)\)
is given by \( |S| \cos(\phi - \theta) \) where \( |S| = \sqrt{\alpha^{2} + \beta^{2}} \) is the
magnitude of spin and \( \phi \) is the angle \( \text{Arg}(\alpha + i\beta) \). After
a simple algebra, we find \( |S| \cos(\phi - \theta) = \alpha \cos \theta + \beta \sin \theta \).
Then given a spin \( S = (\alpha, \beta, 0) \), if one measures the spin
along the direction \((\cos \theta, \sin \theta, 0)\), the measurement re-
glass \( \gamma \) if and only if \( \gamma = \alpha \cos \theta + \beta \sin \theta \). From
this consideration, the probability distribution that the
measurement along the direction \((\cos \theta, \sin \theta, 0)\) gives the value \( \gamma \) is given by

\[
P_{t}^{0}(\gamma) = \int d\alpha d\beta P_{t}^{x,y}(\alpha, \beta) \delta(\gamma - \alpha \cos \theta - \beta \sin \theta).
\]

FIG. 6: The illustration of the dynamics for each harmonic oscillator mode, described by the Hamiltonian Eq. (8). The
initial state contains a large fluctuation of density difference \( \hat{n}_{s,k} \) given by \( \langle \hat{n}_{s,k} \rangle = \eta p / 2(\text{see Eq. (10)}) \),
and its conjugate variable, the phase difference \( \hat{\phi}_{s,k} \), has a small fluctuations. In the subsequent dynamics, such squeezed state
evolves and energy oscillates between the fluctuations of the density difference and phase difference.

monic oscillators given by

\[ \rho_{\phi_{s,k}} = \frac{\pi \rho}{2} \] (see Eq. (10)).

Because of this large fluctuation in the density, almost all the energy of the initial state is stored in the interaction term \( |n_{s,k}|^2 \) in Eq. (8). Therefore, the total energy of each harmonic oscillator can be estimated as \( \frac{\pi \rho}{4} \). During the dynamics dictated by the harmonic oscillator Hamiltonian, this energy oscillates between the density fluctuations and phase fluctuations in a sinusoidal fashion, see Fig. 4. In the dephased limit of the dynamics, approximately equal energy of the system is distributed to the phase and density fluctuations, and from the conservation of energy, we conclude that the characteristic magnitude of phase fluctuation is given by \( \langle |\phi_{s,k}(t)|^2 \rangle \sim \frac{\pi \rho}{4K_s^2} \). Such \( 1/k^2 \) dependence of \( \langle |\phi_{s,k}(t)|^2 \rangle \) agrees with the more rigorous result in Eq. (20). Therefore the spin fluctuations dominantly come from spin waves with long wavelengths, as we have stated in Section III. Moreover, the weak dependence of spin dynamics on high momenta contributions justifies the use of Tomonaga-Luttinger theory for describing the dynamics. We will more carefully analyze the dependence of distributions on the high momentum cutoff in Sec. IV.D.

From the simple argument above, it is also clear that the spin fluctuations coming from spin waves with momenta \( k \) have the time scales associated with the harmonic oscillators given by \( \frac{l}{K_s^2} \). Again, this rough argument agrees with the more rigorous result presented in Eq. (20). Therefore, the fast dynamics is dominated by spin waves with high momenta and slow dynamics is dominated by low momenta. These considerations lead to the illustrative picture of Fig. 2. Furthermore, this implies that the dynamics of the magnitude of spin \( \langle S_z^2(t) \rangle \) reaches a steady state around the time \( \frac{l}{K_s^2} \), since spin waves with wavelength longer than \( l \) do not affect the magnitude. This should be contrasted with the evolution of the \( z \) component of spin which, in principle, keeps evolving until the time scale of \( \frac{L}{\xi_s} \). (see Fig. 4).

The strength of interactions and correlations are associated with Luttinger parameter, \( K_s \). \( K_s \) influences the spin fluctuations \( \langle \phi_{s,k}(t) \rangle \) at all wavelength, and \( \langle |\phi_{s,k}(t)|^2 \rangle \) depends on \( K_s \) as \( 1/K_s^2 \) for a fixed density. As is expected, in the limit of the weak interaction corresponding to large \( K_s \), the amplitude of spin fluctuation decreases. In Fig. 7 we have plotted the time evolution of the joint distributions for \( L/\xi_s = 200 \), \( l/\xi_s = 40 \), and \( K_s = 20, 25 \) and 30. For larger \( K_s \), we see that the spin fluctuations get quickly suppressed.

C. Dynamics of the expectation value of the magnitude of spin \( \langle S_z^2(t) \rangle \)

In order to illustrate the dynamics of the Ramsey sequence further, it is helpful to study the dynamics of the expectation value of the squared transverse magnitude, given by \( \langle S_z^2(t) \rangle \).

In Fig. 8, we plot the evolution of \( \sqrt{\langle S_z^2(t) \rangle} \) with \( K_s = 20 \), \( L/\xi_s = 200 \) and \( l/\xi_s = 20, 30, 40 \). We also plotted \( \langle S_z(t) \rangle \) along with \( \langle S_z^2(t) \rangle \) with the same parameters. It is easy to verify that \( \langle S_z(t) \rangle \) is independent of integration length \( \xi_s \). As we have discussed in the previous section, \( \sqrt{\langle S_z(t) \rangle} \) reach the steady states at the time scale of \( \frac{L}{\xi_s} \) with finite values, while \( \langle S_z^2(t) \rangle \) keeps decaying for much longer time.

\[ S^x = \rho \cos(\hat{\phi}_{s,k}) \] with a small fluctuation of \( \hat{\phi}_{s,k} \), the conjugate variable of \( \hat{n}_{s,k} \). The fluctuation of \( \hat{n}_{s,k} \) is given by \( \langle \hat{n}_{s,k} \hat{n}_{s,-k} \rangle = \eta \rho/2 \) (see Eq. (10)).

Therefore, the total energy of each harmonic oscillator can be estimated as \( \frac{\pi \rho}{4K_s^2} \). During the dynamics dictated by the harmonic oscillator Hamiltonian, this energy oscillates between the density fluctuations and phase fluctuations in a sinusoidal fashion, see Fig. 4. In the dephased limit of the dynamics, approximately equal energy of the system is distributed to the phase and density fluctuations, and from the conservation of energy, we conclude that the characteristic magnitude of phase fluctuation is given by \( \langle |\phi_{s,k}(t)|^2 \rangle \sim \frac{\pi \rho}{4K_s^2} \). Such \( 1/k^2 \) dependence of \( \langle |\phi_{s,k}(t)|^2 \rangle \) agrees with the more rigorous result in Eq. (20). Therefore the spin fluctuations dominantly come from spin waves with long wavelengths, as we have stated in Section III. Moreover, the weak dependence of spin dynamics on high momenta contributions justifies the use of Tomonaga-Luttinger theory for describing the dynamics. We will more carefully analyze the dependence of distributions on the high momentum cutoff in Sec. IV.D.

From the simple argument above, it is also clear that the spin fluctuations coming from spin waves with momenta \( k \) have the time scales associated with the harmonic oscillators given by \( \frac{l}{K_s^2} \). Again, this rough argument agrees with the more rigorous result presented in Eq. (20). Therefore, the fast dynamics is dominated by spin waves with high momenta and slow dynamics is dominated by low momenta. These considerations lead to the illustrative picture of Fig. 2. Furthermore, this implies that the dynamics of the magnitude of spin \( \langle S_z^2(t) \rangle \) reaches a steady state around the time \( \frac{l}{K_s^2} \), since spin waves with wavelength longer than \( l \) do not affect the magnitude. This should be contrasted with the evolution of the \( z \) component of spin which, in principle, keeps evolving until the time scale of \( \frac{L}{\xi_s} \). (see Fig. 4).

The strength of interactions and correlations are associated with Luttinger parameter, \( K_s \). \( K_s \) influences the spin fluctuations \( \langle \phi_{s,k}(t) \rangle \) at all wavelength, and \( \langle |\phi_{s,k}(t)|^2 \rangle \) depends on \( K_s \) as \( 1/K_s^2 \) for a fixed density. As is expected, in the limit of the weak interaction corresponding to large \( K_s \), the amplitude of spin fluctuation decreases. In Fig. 7 we have plotted the time evolution of the joint distributions for \( L/\xi_s = 200 \), \( l/\xi_s = 40 \), and \( K_s = 20, 25 \) and 30. For larger \( K_s \), we see that the spin fluctuations get quickly suppressed.

C. Dynamics of the expectation value of the magnitude of spin \( \langle S_z^2(t) \rangle \)

In order to illustrate the dynamics of the Ramsey sequence further, it is helpful to study the dynamics of the expectation value of the squared transverse magnitude, given by \( \langle S_z^2(t) \rangle \).

In Fig. 8, we plot the evolution of \( \sqrt{\langle S_z^2(t) \rangle} \) with \( K_s = 20 \), \( L/\xi_s = 200 \) and \( l/\xi_s = 20, 30, 40 \). We also plotted \( \langle S_z(t) \rangle \) along with \( \langle S_z^2(t) \rangle \) with the same parameters. It is easy to verify that \( \langle S_z(t) \rangle \) is independent of integration length \( \xi_s \). As we have discussed in the previous section, \( \sqrt{\langle S_z(t) \rangle} \) reach the steady states at the time scale of \( \frac{L}{\xi_s} \) with finite values, while \( \langle S_z^2(t) \rangle \) keeps decaying for much longer time.
FIG. 8: The dynamics of the average value of the magnitude of spins, \( \langle \hat{S}_I^z(t) \rangle \), and the average of the \( x \) component of spins \( \langle \hat{S}_I^x(t) \rangle \). Here \( y \) axis is scaled such that the initial values take the maximum value of 1. Here we took \( L/\xi_s = 200 \), \( K_s = 20 \) and the integration lengths \( l/\xi_s = 20, 30, 40 \). The magnitude of spins decays only due to the spin waves with wavelengths shorter than the integration length \( l \), and the decay of the magnitude stops around the time scale of \( \sim l/\xi_s \). On the other hand, all spin waves contribute to the evolution of the \( x \) component of magnetization, which keeps decaying [68].

It is interesting to ask if the long time limit of \( \langle \hat{S}_I^z(t) \rangle \) for sufficiently large integration length \( l \) attains the value which corresponds to the one expected from the randomization of spin patches of size \( \xi_s \). At low energies, spins within the length \( \sim \xi_s \) are aligned in the same direction, but spin waves can randomize the direction of the spin for each of \( l/\xi_s \) patches. Since the magnitude of spin within \( \xi_s \) is \( \xi_s \rho \), if the patches are completely randomized, the result of the random walk predicts that

\[
\langle \hat{S}_I^z(t) \rangle \sim (\xi_s \rho)^2 (l/\xi_s).
\]

We will see below that, due to the properties of correlations in one dimension, the integrated magnitude of spin \( \langle \hat{S}_I^z(t) \rangle \) never attains this form, albeit a similar expression is obtained (see Eq. [26]). Moreover, we identify the integration length \( \bar{l} \) which separates the "spin diffusion regime" and the "spin decay regime" by finding the decaying length scale for

\[
\langle \hat{S}_I^z(t) \rangle.
\]

The results for the long time limit of \( \langle \hat{S}_I^z(t) \rangle \) can be analytically computed. Following similar steps leading to Eq. [17], we find

\[
\langle \hat{S}_I^z(t) \rangle ^2 = \left| \int dr \rho e^{i\phi(s,r)} \right|^2 = \prod_{i=1}^2 \int_{-l/2}^{l/2} dr_1 \exp \left( -\frac{1}{2} \sum_{k \neq 0} \xi_{s,k} \langle \xi_{s,k} \rangle^* \right).
\]

Here \( \xi_{s,k} = |C_{s,k}| (e^{iK_1} - e^{iK_2}) \). We introduce dimensionless variables \( r_1 = r_1/l_0, k' = kl \) and the integration over \( k \) in the exponent can be carried out as

\[
\int dk' \frac{l}{2\pi l_0} \xi_{s,k'} \left| \langle \xi_{s,k'} \rangle \right|^* = \frac{2}{\pi} \int_{K_{\text{min}}}^{K_{\text{max}}} dk' \left( \frac{1}{|\rho l_0|} \cos^2(|k|c_t) + \pi^2 \rho l_0 \sin^2(|k|c_t) \right) \times \sin^2 \left( \frac{r_1 - r_2}{2} |k'| \right) \approx \frac{k'_0}{2\rho l_0} + \pi^2 \rho l_0 \left| r_1 - r_2 \right| \int_0^\infty dy \frac{\sin^2(y)}{y^2}.
\]

In the second line, we approximated \( \cos^2(|k|c_t) \approx \sin^2(|k|c_t) \approx 1/2 \), which is appropriate for long time.

In the last line, we extended the upper limit of the integration to the second term to \( \infty \) and the lower limit to 0. The former is justified because we know that high momentum contribution is suppressed by \( 1/k_0^2 \), and the latter is justified because we also know low momenta excitations with wavelengths larger than \( l \) do not affect \( \hat{S}_I^z \).

Since \( \int_0^\infty dy \frac{\sin^2(y)}{y^2} = \pi/2 \), we find, in the long time limit,

\[
\langle \hat{S}_I^z(t) \rangle ^2 = \left( \frac{1}{l_0} \right)^2 \left( 1 - \exp(-l_0) \right),
\]

where we expressed the result as a ratio of the asymptotic value and the value at shortest time scale of the theory given by \( t \sim 1/\mu \). \( l_0 = \frac{\pi^2 \rho l_0}{\pi^2 \eta} \) is the dimensionless integration length that controls the value of \( \langle \hat{S}_I^z(t) \rangle \) in the long time limit. As soon as \( l_0 \) becomes larger than 1, the long time value of \( \langle \hat{S}_I^z(t) \rangle \) quickly approach the long integration limit, \( \sim 2 \left( \frac{1}{l_0} - \left( \frac{1}{l_0} \right)^2 \right) \).

An intuition behind the expression for \( l_0 \) can be explained through the following heuristic argument. The system enters the spin decay regime when the spins within the integration length \( l \) rotates by \( 2\pi \) across \( l \). The angle difference between the spins at \( r = 0 \) and
D. Momentum cut-off dependence

The description of dynamics presented above uses the low energy effective theory. In order to confirm the self-consistency of our approach, we check that the distributions of spins are not strongly affected by high energy physics, i.e. they weakly depend on high momentum cutoff. We have seen an indication that this is indeed the case through the weak fluctuations of phases for large $k$, $\left<|\hat{\phi}_{s,k}|^2\right> \propto 1/k^2$, in Sec. IV B.

First of all, we analyze the high momentum cut-off $k_c \sim 2\pi/\xi_s$ dependence of the average value of $\hat{S}_l$. From the discussion in Sec IV B it is straightforward to obtain that (here we ignore $k = 0$ contribution)

$$\left<\hat{S}_l^2\right> = \int_{-l/2}^{l/2} dx \left( e^{i\phi(x)} + e^{-i\phi(x)} \right)$$

$$= \rho \exp \left( -\frac{1}{2} \sum_{k \neq 0} |C_{s,k}|^2 \right),$$

$$\sum_{k \neq 0} |C_{s,k}|^2 = \int_{-k_c}^{k_c} dk \left( \frac{\cos^2(|k|c_s t)}{4\pi\eta} + \frac{\pi\rho\eta}{4k^2K_s^2} \sin^2(|k|c_s t) \right) \approx \frac{k_c}{2\pi\rho\eta} + \frac{\rho\epsilon\eta}{(2K_s/\pi)^2}, \quad (28)$$

where in the last line, we took the long time limit $t \gg \xi_s/c_s$. In this limit, only the first term in Eq. (28) depends on the cutoff $k_c$, and moreover, the cutoff dependence is independent of time. The effect is to reduce the value of $\left<\hat{S}_l^2\right>$ through the multiplication of a number close to one in the weakly interacting limit. For example, if we take $k_c = 2\pi/\xi_s$, then the cut-off dependent term reduces the value by multiplying $\exp \left( -\frac{k_c}{4\pi\rho\eta} \right) \approx e^{-1/(4K_s)} \approx 1$.

In a similar fashion, higher moments of spin operators can be shown to have a weak dependence on the cutoff momentum $k_c$, as long as the integration length is much larger than the healing length, $l/\xi_s \gg 1$. In this limit, moments of, for example, $\hat{S}_l^2$ is reduced by $\exp \left( -m \frac{k_c}{4\pi\rho\eta} \right)$. Therefore, the full distribution function is simply reduced by the multiplication of a number close to one $\exp \left( -\frac{k_c}{4\pi\rho\eta} \right) \approx e^{-1/(4K_s)} \approx 1$ in the weakly interacting regime. This gives the self-consistency check of our results in Sec IV B.

V. DYNAMICS OF FULL DISTRIBUTION FUNCTION IN THE PRESENCE OF MIXING BETWEEN SPIN AND CHARGE DEGREES OF FREEDOM

In this section, we extend the analysis in Sec IV to a more general case, in which spin and charge degrees of freedom mix. We will see that the distribution functions even for this more general case have essentially the same structure as in Eq. (21), and are described by spin waves with fluctuations whose amplitude is determined by the fluctuations of phase $\left<|\hat{\phi}_{s,k}|^2\right>$. One important difference from the decoupling case is the dependence of spin distributions on the initial temperature of the system. The thermal excitations are present in the charge degrees of freedom in the initial state, and such thermal fluctuations increase the value of $\left<|\hat{\phi}_{s,k}|^2\right>$ through the coupling between spin and charge during the evolution.
A. Hamiltonian and initial state

In a generic system of two component bosons in one dimension, spin and charge degrees of freedom couple through the mixing Hamiltonian in Eq.(7). Yet, Hamiltonian in Eq.(4) is still quadratic and it can be diagonalized. We define new operators \( \hat{\phi}_1, \hat{\phi}_2, \hat{n}_1, \hat{n}_2 \) by

\[
\begin{align*}
(\hat{\phi}_1 & = (\cos \kappa \sin \kappa
- \sin \kappa \cos \kappa) \left( \sqrt{s_c} \hat{\phi}_s \right), \\
(\hat{n}_1 & = (\cos \kappa \sin \kappa
- \sin \kappa \cos \kappa) \left( \frac{1}{\sqrt{s_c}} \hat{n}_c \right).
\end{align*}
\tag{29}
\tag{30}
\]

Mixing angle \( \kappa \) and scaling parameter \( s_c \) are chosen so that the Hamiltonian is written in the following diagonal form

\[
H = H_1 + H_2,
\tag{31}
\]

\[
H_1 = \int_{-L/2}^{L/2} dr \frac{\rho}{2m'} (\nabla \hat{\phi}_1(r))^2 + g_1(\hat{n}_1)^2,
\]

\[
H_2 = \int_{-L/2}^{L/2} dr \frac{\rho}{2m'} (\nabla \hat{\phi}_2)^2 + g_2(\hat{n}_2)^2.
\]

Explicitly, \( \kappa \) and \( s_c \) are given by

\[
s_c = \frac{g_{mix} + g_s \hat{\phi}_3}{g_{mix} + \frac{g_{mix}^2}{2m}}, \quad \tan \kappa = \frac{-\kappa_0 \pm \sqrt{\kappa_0^2 + 4}}{2},
\]

\[
\kappa_0 = \frac{g_c - g_s}{\sqrt{s_c} g_{mix}},
\]

where \( \pm \) in the expression of \( \tan \kappa \) is + when \( \kappa_0 > 0 \) and - when \( \kappa_0 < 0 \). We defined \( \kappa \) such that \( \kappa = 0 \) corresponds to decoupling of charge and spin, i.e. to \( g_{mix} = 0 \) and \( g_{mix}^2 = 0 \) in Eq. (7). Parameters \( g_1, g_2, \frac{\rho}{2m} \) and \( \frac{\rho}{2m} \) are given by

\[
g_1 = s_c g_c + \sqrt{s_c} \tan \kappa g_{mix},
\]

\[
g_2 = g_s - \frac{\rho}{2m_s} \tan \kappa g_{mix},
\]

\[
\frac{\rho}{2m_1} = \frac{g_c}{2m_s} + \frac{\kappa_0 g_{mix}}{\sqrt{s_c}},
\]

\[
\frac{\rho}{2m_2} = \frac{g_s}{2m_s} - \frac{\kappa_0 g_{mix}}{\sqrt{s_c}}.
\]

In the weakly interacting systems which we study in this paper, Luttinger parameters \( K_i \) and sound velocities \( c_i \) are determined for each Hamiltonian \( H_i, i = \uparrow, \downarrow, c, s, 1, 2 \) through

\[
K_i = \pi \frac{\rho}{2m_i g_i}, \quad c_i = \frac{\rho g_i}{m_i}.
\tag{32}
\]

At finite temperature, the state before the first \( \pi/2 \) pulse contains excitations, and these excitations are carried over to the charge degrees of freedom after the pulse.
with $2W_k = \frac{1 - \alpha_k}{1 + \gamma_0}$ and $\alpha_k = \frac{|k|/\rho_0}{\rho_0}$ as before. The second operator is the operator of charge degrees of freedom, and it is given by

$$
\gamma_{c,k}(t) = e^{-itH} \gamma_{c,k}(0)e^{itH},
$$

$$
\gamma_{c,k}(0) = b_{c\downarrow,k}.
$$

where $b_{c\uparrow,k}$ is an annihilation operator for the elementary excitations in $H_{c\uparrow}$. Since $\gamma_{s,k}(t)$ and $\gamma_{c,k}(t)$ commute at $t = 0$, they commute at any time $t$. We will drop the time dependence of $\gamma_{a,k}(t)$ in the notation from now on.

From the expression of initial density matrix $\rho_0$ in Eq. (34), it is easy to check that the density matrix at time $t$ given by $\hat{\rho}(t) = e^{-itH} \rho_0 e^{itH}$ can be written as the tensor product of the density matrix of operators $\gamma_{s,k}(t)$ and that of $\gamma_{c,k}(t)$. This is because $\rho_0$ is a tensor product of the density matrices of $\gamma_{s,k}(t = 0)$ and that of $\gamma_{c,k}(t = 0)$. This structure of the density matrices at time $t$ allows the independent evaluation of $\gamma_{s,k}(t)$ and $\gamma_{c,k}(t)$ operators, and it is advantageous to express spin operators in terms of these operators.

As we show in the Appendix B we can write $\hat{\phi}_{s,k}$ in terms of $\gamma_{s,k}(t)$ and $\gamma_{c,k}(t)$ as follows.

$$
\frac{1}{\sqrt{L}} \hat{\phi}_{s,k} = C_{s,k} \gamma_{s,k} + C_{c,k} \gamma_{c,k},
$$

where explicit expression of $C_{s,k}$ and $C_{c,k}$ are given by

$$
C_{s,k} = \frac{i}{\sqrt{2L/\rho_0}} \left( \cos^2 \theta \cos(c_2|k|t) + \sin^2 \theta \cos(c_1|k|t) \right) - \frac{K_s}{\alpha_k} \left( \frac{\cos^2 \theta \sin(c_2|k|t)}{K_2} + \frac{\sin^2 \theta \sin(c_1|k|t)}{K_1} \right),
$$

$$
C_{c,k} = \cos \theta \sin \theta \sqrt{\frac{2L}{|s|_c K_c \uparrow}} \left( i \{ \cos(c_1|k|t) - \cos(c_2|k|t) \} - \bar{K}_{c\uparrow} \left( \frac{\sin(c_2|k|t)}{K_2} - \frac{\sin(c_1|k|t)}{K_1} \right) \right),
$$

where $K_{c\uparrow} = K_{c\uparrow}/\sqrt{s_c}$.

Using Eq. (35), we find an expression for $(\hat{S}_{\downarrow}^a)^m$ in terms of $\gamma_{a,k}$ with $a = s, c$ as follows

$$
(\hat{S}_{\downarrow}^a)^m = \prod_{i=1}^m \int_{-\frac{1}{2}}^{\frac{1}{2}} dr_i \frac{\rho_0}{\pi} \sum_{\{s_i\}} e^{i \sum_{k \neq 0} (\xi_{s,k}\gamma_{s,k} + \xi_{c,k}\gamma_{c,k})} e^{i \sum_{k \neq 0} (\xi_{s,k}\gamma_{s,k}^\dagger + \xi_{c,k}\gamma_{c,k}^\dagger)} e^{i(S_{\downarrow}^a_0/\sqrt{\mathcal{T}}) e^{-i(S_{\downarrow}^a_0/\sqrt{\mathcal{T}})},}
$$

where $\xi_{s,k} = (\sum_{i=m}^m s_i e^{ir_i,k})C_{s,k}$. In the following, we separately evaluate three contributions; $k = 0$ component given by $e^{i(S_{\downarrow}^a_0/\sqrt{\mathcal{T}})}$, the charge component of $k \neq 0$ given by $e^{i \sum_{k \neq 0} (\xi_{s,k}\gamma_{s,k}^\dagger + \xi_{c,k}\gamma_{c,k})}$, the spin component of $k \neq 0$ given by $e^{i \sum_{k \neq 0} (\xi_{s,k}\gamma_{s,k}^\dagger + \xi_{c,k}\gamma_{c,k})}$.

1. $k = 0$ contribution

The initial state of $k = 0$ spin sector in Eq. (12) as well as that of the charge sector in Eq. (33) both have a Gaussian form so that calculation of the trace $\text{Tr} \left\{ e^{i(\xi_{s,k}\gamma_{s,k} + \xi_{c,k}\gamma_{c,k})} \right\}$ is straightforward. We leave the details to the Appendix C and the result is

$$
\langle e^{i(S_{\downarrow}^a_0/\sqrt{\mathcal{T}})} \rangle = \exp \left( - \sum_{s} s_i \right) \frac{\langle \phi_{s,0}^2 \rangle_i}{2L}
$$

$$
\langle \phi_{s,0}^2 \rangle_i = \frac{1}{\rho_0} \left( \sin^2 \theta \frac{\pi c_1}{K_1} + \cos^2 \theta \frac{\pi c_2}{K_2} \right)^2 \frac{\rho_0}{2} + \sin^2 \theta \cos^2 \theta \frac{\pi c_1}{K_1} - \frac{\pi c_2}{K_2} \frac{\bar{K}_{c\uparrow}}{\bar{K}_{c\uparrow}} \frac{\rho_0}{2} \frac{\rho_0}{2}.
$$

2. $k \neq 0$, spin sector

This calculation is analogous to Eq. (17) and the result can be directly read off from Eq. (17), and it is

$$
\langle e^{i \sum_{k \neq 0} (\xi_{s,k}\gamma_{s,k}^\dagger + \xi_{c,k}\gamma_{c,k})} \rangle = \exp \left( - \frac{i}{2} \sum_{k \neq 0} \xi_{s,k}^* \xi_{s,k} \right).
$$
3. \( k \neq 0 \), charge sector

We first rewrite the density matrix at time \( t \) as

\[
\hat{\rho}_{c,k \neq 0}(t) = e^{-iHt} e^{-\beta c_{cT} \sum_{k \neq 0} |k\rangle \langle k|_{c\rightarrow c} e^{iHt} / \mathcal{N},
\]

where \( \mathcal{N} \) is normalization given by \( \mathcal{N}_c = \text{Tr} e^{-\beta c_{cT} \sum_{k \neq 0} |k\rangle \langle k|_{c\rightarrow c} (t)} = \prod_{k \neq 0} -1/\lambda_k \) with \( \lambda_k = e^{-\beta c_{cT}|k|} - 1 \).

Then the trace of \( \left( \hat{S}_f^0 \right)^m \) for \( k \neq 0 \) spin sector is

\[
\langle e^{i \sum_{k \neq 0} (\xi_{c,k}^* \gamma_{c,k} + \xi_{c,k} \gamma_{c,k})} \rangle = \prod_{k \neq 0} \text{Tr} e^{i (\xi_{c,k}^* \gamma_{c,k} + \xi_{c,k} \gamma_{c,k})} e^{-\beta |k|_{c\rightarrow c} \gamma_{c,k} | \mathcal{N}
\]

We can evaluate this by taking the trace in the basis of normalized coherent states \( |\alpha_k\rangle \) such that \( \gamma_{c,k} |\alpha_k\rangle = \alpha_k |\alpha_k\rangle \). The use of the identity \( 1 = \frac{1}{2} \int d^2 \alpha_k |\alpha_k\rangle \langle \alpha_k| \) as well as of an important equality \( e^{\pi \alpha a^\dagger a} = e^{(e^{-\pi} - 1)a^\dagger a} \), where \( \mathcal{O} \) is a normal ordering of \( \mathcal{O} \), leads to

\[
\langle e^{i \sum_{k \neq 0} (\xi_{c,k}^* \gamma_{c,k} + \xi_{c,k} \gamma_{c,k})} \rangle
\]

4. Full distribution function

We can summarize the results above as

\[
\langle (\hat{S}_f^0)^n \rangle = \sum_{\{s_i\}} \prod_{i=1}^m \int dr_i \frac{\rho}{2} \exp \left( -\frac{1}{2} \sum_{k \neq 0} M_{c,k} \xi_{c,k}^* \xi_{c,k} \right) \exp \left( -\frac{1}{2} \sum_{k \neq 0} M_{c,k} \xi_{c,k}^* \xi_{c,k} \right) \exp \left( -\frac{1}{2} \left( \sum_i s_i \right)^2 \frac{\phi_s^2 1}{L} \right) e^{-i (\sum_i s_i)^\theta} (41)
\]

Here, \( M_{c,k} = \frac{1+e^{-\beta |k|_{c\rightarrow c}}}{1-e^{-2\beta |k|_{c\rightarrow c}}} \). As before, we introduce the auxiliary variables to separate spatial integrations over \( r_i \). We can combine \( \xi_{c,k}^* \xi_{c,k} \) and \( M_{c,k} \xi_{c,k}^* \xi_{c,k} \) so that we only need to introduce three sets of variables, \( \lambda_{1,s,k}, \lambda_{2,s,k}, \lambda_0 \) for Hubbard-Stratonovich transformation. Summing over \( \{s_i\} \) simplifies the result, leading to the following expression for the full distribution function

\[
P_f^\theta(\alpha) = \Pi_k \frac{e^{-\pi \alpha c_{cT} |k|}}{2 \pi} \int_0^\infty \lambda_{rsk} e^{-\lambda_{rsk}^2/2} d\lambda_{rsk} \times \delta \left( \alpha - \rho \frac{1/2}{L} dr \cos \left( \chi \{r, \{\lambda_{jsk}\} \} - \theta \right) \right)
\]

\[
\chi \{r, \{\lambda_{jsk}\} \} = \sum_k \sqrt{\frac{|\phi_{s,k}|^2}{L}} \lambda_{rsk} \sin(kr + \lambda_{rsk}),
\]

\[
|\phi_{s,k}|^2 / L = |C_{s,k}|^2 + \frac{1+e^{-\beta |k|_{c\rightarrow c}}}{1-e^{-2\beta |k|_{c\rightarrow c}}} |C_{s,k}|^2, \quad k \neq 0
\]
FIG. 9: Time evolution of the joint distribution function $P^{x,y}(\alpha,\beta)$ for the system size $L/\xi_s = 400$, the spin Luttinger parameter $K_s = 20$ and integration length $l/\xi_s = 20$ in the presence of mixing between the spin and charge modes. For a), the interaction strength ratio is taken to be $g_c : g_s : g_{\text{mix}} = 1 : 1 : 0.1$, and for b), $g_c : g_s : g_{\text{mix}} = 1 : 1 : 0.3$. Time is measured in units of $\xi_s/c_s$ where $c_s$ is the spin sound wave velocity. Here axes are scaled such that the maximum value of $\alpha$ and $\beta$ are 1. With increasing strength of mixing, the large initial temperature affects the spin dynamics at earlier time more strongly.

The last line can be confirmed by directly computing $\expval{\hat{\phi}_{s,k}^2}$, using the expression in Eq. (35). The expression for $\expval{\hat{\phi}_{s,0}^2}$ is given by Eq. (37). As before, the joint distributions as well as the distributions of squared transverse magnitude can be obtained through the same procedure as in Sec. IV B 4.

The spin distribution in the presence of mixing between spin and charge degrees of freedom resembles the one in the absence of such mixing, and the only change is the additional contributions to phase fluctuations coming from the thermal excitations, represented by $\frac{1+e^{-\beta|k|c_s}}{1-e^{-\beta|k|c_s}} |C_{c,k}|^2$ in Eq. (41). $|C_{c,k}|$ is proportional to $\sin^2 \kappa$ as one can see from Eq. (36). Thus, for weak coupling of $\kappa \sim 0$, the contribution is diminished by a factor of $\kappa^2$.

In the experiment by Widera et al., they used Rb$^{87}$ in the presence of Feshbach resonance. They employed the theory which assumes the absence of mixing between spin and charge degrees of freedom to analyze the decay of the Ramsey fringes. The ratio of interaction strengths in their experiment can be roughly estimated as $g_c : g_s : g_{\text{mix}} \approx 3.66 : 0.34 : 0.06$ which leads to the value of $\kappa \approx 2 \times 10^{-2}$. Therefore, the thermal contributions are diminished by about four order of magnitude and thus, their assumption of decoupling between spin and charge is justified.

In Fig. we have plotted the evolution of the joint distribution functions for different strength of the coupling $g_{\text{mix}}$ at a relatively large initial temperature $k_B T = 0.4 \times 2\pi c_s/\xi_s$ where $2\pi c_s/\xi_s$ is approximately the high energy cut-off of Tomonaga-Luttinger theory. Here we took the system size $L/\xi_s = 400$, the Luttinger parameter $K_s = 20$, integration length $l = 20\xi_s$. For Fig. a), the ratio of interaction is taken to be $g_c : g_s : g_{\text{mix}} = 1 : 1 : 0.1$, and for b), $g_c : g_s : g_{\text{mix}} = 1 : 1 : 0.3$. One can see that with increasing strength of mixing, the large initial temperature affects the spin dynamics at earlier time more strongly. For comparison, also see Fig. 4.

VI. INTERFERENCE OF TWO ONE-DIMENSIONAL CONDENSATES

A. Dynamics of interference pattern

As we have described in Sec. II B, the full distribution of interference patterns can be studied in exactly the same way as we have studied the full distribution of spins in previous sections. In the following, we more formally describe the dynamics of split condensates.

The low energy effective Hamiltonian of two quasi-
condensates after splitting is given by
\[ H = H_L + H_R, \]  
\[ H_L = \int_{-L/2}^{L/2} dr \left( \frac{\rho_L}{2m} (\nabla \hat{\phi}_L(r))^2 + \frac{g}{2}(\hat{n}_L(r))^2 \right), \]  
\[ H_R = \int_{-L/2}^{L/2} dr \left( \frac{\rho_R}{2m} (\nabla \hat{\phi}_R(r))^2 + \frac{g}{2}(\hat{n}_R(r))^2 \right), \]
where we assumed weakly interacting bosons with a possible density difference \( \rho_R - \rho_L \neq 0 \) between the two condensates. Here and in the following, we consider the rotating frame and ignore the chemical potential difference \( g/2(\rho_R - \rho_L) \) between left and right condensates arising from interactions.

The interference pattern measures the phase difference \( \phi_L - \phi_R \). We describe the system in terms of the "spin" variables that are the difference of left and right condensates and "charge" variables that are the sum of the two. Using the variables \( \phi_s = \phi_R - \phi_L \), \( \phi_c = \phi_R + \phi_L \), \( \hat{n}_s = (\hat{n}_R - \hat{n}_L)/2 \), \( \hat{n}_c = (\hat{n}_R + \hat{n}_L)/2 \), we find the Hamiltonian of the system to be
\[ H = H_s + H_c + H_{\text{int}} \]  
\[ H_s = \int dx \left( \frac{\rho_R + \rho_L}{8m} (\partial_x \phi_s)^2 + g\hat{n}_s^2 \right), \]  
\[ H_c = \int dx \left( \frac{\rho_R + \rho_L}{8m} (\partial_x \phi_c)^2 + g\hat{n}_c^2 \right), \]  
\[ H_{\text{int}} = \int dx \left( \frac{\rho_R - \rho_L}{4m} \partial_x \phi_c \partial_x \phi_s \right). \]

Therefore, when the splitting makes two identical quasi-condensates with equal density, "spin" and "charge" degrees of freedom decouple and we can use a simpler theory derived in Sec \[\text{V}\] On the other hand, when the splitting makes two condensates with unequal densities, more general theory of Sec \[\text{V}\] needs to be employed. In any case, the full time evolution of the distributions of interference patterns can be obtained, which in principle can be compared with experiments.

It is notable that the mixing of the "spin" and "charge" degrees of freedom for small density difference \( \rho_R - \rho_L \) is not "small," in the sense that the mixing angle \( \kappa \) defined in section \[\text{V}\] takes the maximum value \( \pi/4 \). The spin decoupling in the limit of \( \rho_R - \rho_L \rightarrow 0 \) is recovered not by taking \( \kappa \rightarrow 0 \), but rather, by taking the time at which the effect of the coupling takes place to infinity. This is most explicitly shown in Eq. (36) where the charge contributions of fluctuations go to zero as \( c_1 \rightarrow c_2 \) which is attained in the limit \( \rho_R - \rho_L = 0 \).

B. Interference patterns in equilibrium

The techniques to calculate the full distribution functions presented in previous sections are directly applicable to also obtaining a simple form of the full distribution functions of the interference patterns between two independent, thermal quasi-condensates. This problem has been previously analyzed in theory \[63, 70\] as well as in experiments \[13, 21\].

We consider the preparation of two independent one-dimensional quasi-condensates. If they are prepared by cooling two independent quasi-condensates, the temperature of the left quasi-condensate \( T_L \) and that of right quasi-condensate \( T_R \) are generically different. The density matrix of the initial state is described by \( \rho_0 = e^{-(\beta_H L) + \beta_H R)} \) where \( \beta_a = 1/(\hbar^2 T_a) \) with \( a = L, R \). It is important to note that the constant shift of phase \( \phi_a \rightarrow \phi_a + \theta_{ac} \) does not change the energy of the system, so that for the average over thermal ensemble one has to integrate over \( \theta_{ac} \). Physically, this simply means that the phases of independent condensates are random. Then the only interesting distribution here is the distribution of the interference contrast \[13, 18, 26, 69\] given by,
\[ C^2 = \left| \int_{-L/2}^{L/2} e^{-i\hat{\phi}_s(r)} dr \right|^2 \]
which corresponds to, in spin language, the squared transverse magnitude of the spin \( \langle \hat{S}_s^2 \rangle \). The analysis of the evaluation of distributions in the density matrix of thermal equilibrium state in Sec \[\text{V}\] can be directly extended to this case, and we obtain the distribution
\[ D_L(\gamma) = \prod_k \int_{-\pi}^{\pi} \frac{d\theta_{sk}}{2\pi} \int_0^\infty \lambda_{rsk} e^{-\lambda^2_{rsk}/2} d\lambda_{rsk} \]
\[ \times \delta \left( \gamma - \left| \rho \int_{-L/2}^{L/2} dr e^{i\chi(r, \{j_{sk}\})} \right|^2 \right), \]
\[ \chi(r, \{j_{sk}\}) = \sum_k \sqrt{\frac{\langle |\hat{\phi}_{s,k}|^2 \rangle}{L}} \lambda_{rsk} \sin(k r + \lambda_{sk}), \]
\[ \langle |\hat{\phi}_{s,k}|^2 \rangle = \frac{1 + e^{-\beta_0 |k| c_a}}{1 - e^{-\beta_0 |k| c_a}} \frac{\pi}{2|k| K_L} + \frac{1 + e^{-\beta_0 |k| c_a}}{1 - e^{-\beta_0 |k| c_a}} \frac{\pi}{2|k| K_R}, \]
where \( c_a \) and \( K_a \), \( a = L, R \) are the sound velocity and Luttinger parameters of left and right quasi-condensate.

C. Prethermalization of interference patterns

In Sec \[\text{HTC}\] we gave a heuristic argument for prethermalization phenomena, where the distribution of the interference contrast amplitudes of the two non-equilibrium quasi-condensates are given by that of two equilibrium quasi-condensates at some effective temperature \( T_{\text{eff}} \). We identified the effective temperature to be the energy
stored in each momentum mode. In Sec. [V B 3] we found this energy to be \( \frac{\pi \rho n}{4K_s} \), thus we conclude \( k_B T_{\text{eff}} = \frac{\pi \rho n}{4K_s} \).

In the following, we formally derive the result above, using the expressions of full distributions of interference patterns. The distribution of the interference contrast is determined by \( \langle |\hat{\phi}_{s,k}|^2 \rangle \) given in Eq. (20). In the long time limit, we can take \( \sin^2(c_s|k|t) \sim \cos^2(c_s|k|t) \sim 1/2 \). Moreover, since the interference contrast is most affected by the excitations with small wave vectors \( k \) with \( \alpha_k = \frac{|\xi_k|}{\pi \rho n} < 1 \), we can approximate the expression as

\[
\langle |\hat{\phi}_{s,k}|^2 \rangle \approx \frac{\pi}{2|k|K_s} \frac{\pi \rho n}{2|k|K_s}. \tag{50}
\]

On the other hand, for two quasi-condensates in thermal equilibrium, the position of the interference peaks is again random. The interference contrast is determined by \( \langle |\hat{\phi}_{s,k}|^2 \rangle \) given in Eq. (49). Since the main contribution to the fluctuation comes from low momenta, we approximate \( e^{-\beta|k|c} \approx 1 - \beta|k|c \). It is easy to check that the sound velocity and Luttinger parameters for each condensate is related to those of the difference mode (see Eqs. (49)-(46) as \( c_L = c_R = c_s \) and \( K_L = K_R = 2K_s \). Thus we obtain

\[
\langle |\hat{\phi}_{s,k}|^2 \rangle \approx \frac{2}{\beta|k|c_s} \frac{\pi}{2|k|K_s}. \tag{51}
\]

Now the crucial observation is that our closed form expressions for distributions of interference contrasts of both split quasi-condensates and thermal quasi-condensates are determined solely by \( \langle |\hat{\phi}_{s,k}|^2 \rangle \), and they take precisely the same form in terms of \( \langle |\hat{\phi}_{s,k}|^2 \rangle \). Moreover, the expressions given by Eq. (50) and Eq. (51) have the same dependence on wave vectors \( |k| \). Therefore, the full distribution of interference contrast of split condensates become indistinguishable from that of thermal condensates with temperature

\[
k_B T_{\text{eff}} \approx \frac{\pi \rho n}{4K_s} = \frac{\mu n}{2}, \tag{52}
\]

where the second equality holds for weakly interacting bosons and the chemical potential of one quasi-condensate is given by \( \mu = gp \). Thus, split one dimensional quasi-condensates indeed display the prethermalization phenomenon.

In Fig. 10, we plot the interference contrast \( P_i^\perp(\gamma) \) (see Eq. (29)) of split condensates in a steady state at time \( t = 60\xi_s/c_s \) for Luttinger parameter \( K_s = 20 \), system size \( L = 400\xi_s \) and two different integration lengths \( l/\xi_s = 30, 40 \). Also we plot the interference contrast of the thermal quasi-condensates (see Eq. (18)) at temperature \( \frac{\pi \rho n}{4K_s} \) for the same integration length. This temperature corresponds to the effective temperature obtained in Eq. (52). Indeed we see only a small difference between the distributions of steady states and thermal states for both integration lengths. The small difference comes from the approximations made in obtaining the expressions given by Eq. (50) and Eq. (51).

In the previous paragraphs, we assumed that the splitting prepares quasi-condensates with identical average densities. Here we briefly consider the case in which the splitting process prepares two quasi-condensates with slightly different densities. In this case, the temperature of the initial quasi-condensates affects the interference contrast around the time scale \( \frac{L}{(\xi_L - \xi_R)^2} \approx \frac{\mu}{(\frac{\mu}{c_s})^2} \), whereas the prethermalized, long-time transient state is reached around \( \frac{L}{n \xi_s} \), where \( l \) is the integration length.

These analytic arguments can be confirmed through numerical simulations. In Fig. 11, we have plotted the evolution of the interference contrast \( C^2 \) for system size \( L = 500\xi_s \), integration length \( l = 40\xi_s \), and Luttinger parameter \( K_s = 20 \) with initial temperature corresponding to the chemical potential \( \mu \). Here we consider a situation where the density of left quasi-condensate is different from that of right quasi-condensate by 20% such that \( \rho_R = 1.2\rho \) and \( \rho_L = 0.8\rho \) where \( \rho_{R(L)} \) is the average density of the right (left) condensate, and \( 2\rho \) is the average density of the initial condensate before splitting. Also for comparison we have plotted the magnitude of interference contrast of two quasi-condensates in thermal states at temperature given by \( \mu \). From the plot, one can observe the existence of quasi-steady state plateau after short time. Notice that the magnitude of \( C^2 \) in the steady state is larger than the value expected from thermalized states at the initial temperature. The subsequent slow decrease of the interference contrast is due to the effect of temperature in the initial state coming from the small difference of the two quasi-condensates. Such development of the plateau at larger value of interference...
of interest to extend our analysis to higher spins[72], and analyze them, for example, in the presence of magnetic field[73]. Since there are more degrees of freedom in these systems, distributions might capture the tendency towards various phases such as ferromagnetic ordering. These questions will be analyzed in the future works.

APPENDICES

Appendix A: Distribution function of the $z$ component of spin

In this appendix, we calculate the distribution function of $\hat{S}_z^\rho$ in the absence of the coupling between charge and spin. The extension to the case in which the charge and spin degrees of freedom mix is straightforward.

It is convenient to evaluate the generating function $\langle e^{\lambda \hat{S}_z^\rho} \rangle$, instead of distribution function $P_l^\rho(\alpha)$. They are related by

$$\langle e^{\lambda \hat{S}_z^\rho} \rangle = \int_{-\infty}^{\infty} e^{\lambda \alpha} P_l^\rho(\alpha) d\alpha. \quad (A1)$$

This equality can be checked by differentiating both sides by $\lambda$ and evaluating them at $\lambda = 0$. This reproduces the implicit definition of $P_l^\rho$ in Eq. (2).

Analogous to the calculation of $m$th moment of $\hat{S}_z^\rho$, we first express $\hat{S}_z^\rho$ in terms of $\gamma_{s,k}$ operators defined in Eq. (15)

$$\hat{S}_z(r) = \int_{-l/2}^{l/2} dr \left( \sum_{k \neq 0} (d_{s,k} \gamma_{s,k}^+ + d_{s,k}^* \gamma_{s,-k}) e^{ikr} + n_{s,0} \sqrt{L} \right),$$

$$d_{s,k} = \sqrt{|k|/2\pi L} e^{-ikr} \left( |k| e^{-ikr} + 2W_k e^{-ikr} \right).$$

Then, we can apply the trick introduced in Section IV B to obtain

$$\langle e^{\lambda \hat{S}_z^\rho} \rangle = e^{\lambda^2 \iint |dr_1| |dr_2| \sum_{k \neq 0} |d_{s,k}|^2 e^{ik(r_1 - r_2)} + \frac{(n_{s,0}^2)}{c^2}} \cdot$$

$$= \exp \left\{ \lambda^2 \iint |dr_1| |dr_2| \sum_{k \neq 0} \frac{|d_{s,k}|^2}{k^2} \sin^2(\frac{lk}{2}) \right\}.$$
Then the following expression gives the distribution of $\hat{S}_i^z$

$$P_i^z(\alpha) = \frac{1}{2 \pi} \left( \frac{\alpha^2}{\left\langle \left( \hat{S}_i^z \right)^2 \right\rangle} \right)^{1/2} \exp \left( -\frac{\alpha^2}{4 \left\langle \left( \hat{S}_i^z \right)^2 \right\rangle} \right), \quad (A2)$$

where

$$\left\langle \left( \hat{S}_i^z \right)^2 \right\rangle = \frac{\hbar^2}{L} + \sum_{k \neq 0} \frac{4 |d_{a,k}|^2}{k^2} \sin^2 (lk/2).$$

Appendix B: Expression for $C_{a,k}$ in the presence of mixing between charge and spin

In this section, we derive the expression of $C_{a,k}, a = s, c$ in Eq. (35). We first find the transformation from $b_{s,k}, b_{c,k}\uparrow, b_{1,k}, b_{2,k}\uparrow$ to $b_{1,k}, b_{2,k}$ and $\gamma_{s,k}(t), \gamma_{c,k}(t)$. Then we relate $b_{1,k}, b_{2,k}$ and $\gamma_{s,k}(t), \gamma_{c,k}(t)$. Combining these two transformations, we obtain $b_{s,k}$ in terms of $\gamma_{s,k}(t), \gamma_{c,k}(t)$, leading to the expression of $\phi_{s,k}$ in terms of $\gamma_{s,k}(t), \gamma_{c,k}(t)$.

From the relations,

$$\phi_{1,k} = -i \sqrt{\frac{\pi}{2|k|K_i}} (b_{1,k}^\dagger - b_{1,-k}),$$

$$n_{1,k} = \sqrt{|k|K_i} \left( b_{1,k}^\dagger + b_{1,-k} \right),$$

$$b_{1,k}^\dagger = i \phi_{1,k} \sqrt{\frac{|k|K_i}{2\pi}} + n_{1,k} \sqrt{\frac{\pi}{2|k|K_i}},$$

along with Eq. (29), it is straightforward to obtain

$$\begin{pmatrix}
    b_{c,\uparrow,-k} \\
    b_{c,\uparrow,k} \\
    b_{s,-k} \\
    b_{s,k}
\end{pmatrix} = D \begin{pmatrix}
    b_{1,k}^\dagger \\
    b_{1,k} \\
    b_{2,-k}^\dagger \\
    b_{2,-k}
\end{pmatrix},$$

where

$$D = \frac{1}{2} \begin{pmatrix}
    \cos \kappa \left( \sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & \cos \kappa \left( -\sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & -\sin \kappa \left( \sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & -\sin \kappa \left( -\sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) \\
    \cos \kappa \left( -\sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & \cos \kappa \left( \sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & -\sin \kappa \left( -\sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & -\sin \kappa \left( \sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) \\
    \sin \kappa \left( \sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & \sin \kappa \left( -\sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & \cos \kappa \left( \sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & \cos \kappa \left( -\sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) \\
    \sin \kappa \left( -\sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & \sin \kappa \left( \sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & \cos \kappa \left( -\sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right) & \cos \kappa \left( \sqrt{\frac{\kappa_{++}}{\kappa_i}} + \sqrt{\frac{\kappa_{--}}{\kappa_i}} \right)
\end{pmatrix}, \quad (B1)$$

Now define a matrix $G(k) = DE_k^{-1}$ so that

$$\begin{pmatrix}
    b_{c,\uparrow,-k} \\
    b_{c,\uparrow,k} \\
    b_{s,-k} \\
    b_{s,k}
\end{pmatrix} = G(k) \begin{pmatrix}
    \gamma_{c,-k} \\
    \gamma_{c,k} \\
    \gamma_{s,-k} \\
    \gamma_{s,k}
\end{pmatrix}.$$ 

Then finally $C_{s,k}$ are given by

$$C_{s,k} = -i \sqrt{\frac{\pi}{2L|k|K_s}} (G_{34}(k) - G_{43}(k)),$$

$$C_{c,k} = -i \sqrt{\frac{\pi}{2L|k|K_s}} (G_{32}(k) - G_{42}(k)), \quad (B2)$$

where $G_{ij}(k)$ are the matrix elements of $G(k)$.

Appendix C: $k = 0$ contribution in the presence of mixing between charge and spin

In this appendix, we evaluate $\text{Tr} \left\{ e^{i\sum s_k \phi_{s,k} / \sqrt{T} \rho(t)} \right\}$.

We first obtain the operator $e^{i\sum s_k \phi_{s,k}}$ after time evo-
Now that we know the operator after time-evolution Eq. (C1), we evaluate it in the initial state.

Initial state of the spin sector is $|\psi_{s,k=0}\rangle$ in Eq. (12). Since this state is Gaussian, we have the simple result as follows,

$$\langle \psi_{s,k=0} | \exp \left( \sum_{i} s_{i} \left( A \phi_{s,0} + A^{\dagger} n_{s,0} + \frac{B}{\sqrt{c}} \phi_{c,0} + \frac{B^{\prime}}{\sqrt{c}} n_{c,0} \right) \right) | \psi_{s,k=0}\rangle = \exp \left( - \left( \sum_{i} s_{i} \right)^{2} \left( \frac{1}{4\eta L} + \left( A^{\prime} \right)^{2} \frac{\eta}{4L} \right) \right) ,$$

For charge sector, $k = 0$ part of the initial density matrix is $\frac{1}{N_{c0}} \exp \left( - \frac{\pi c_{c}^{2}}{2K_{c}^{\prime}} n_{c,0}^{2} \right)$, where $N_{c0}$ is the normalization $N_{c0} = \text{Tr} \left( \exp \left( - \frac{\pi c_{c}^{2}}{2K_{c}^{\prime}} n_{c,0}^{2} \right) \right)$. The evaluation of the charge sector yields

$$\frac{1}{N_{c0}} \text{Tr} \left\{ \exp \left( \left( \sum_{i} s_{i} \right) B^{\prime} \frac{n_{c,0}}{\sqrt{c_{c}L}} \right) \exp \left( - \frac{\pi c_{c}^{2}}{2K_{c}^{\prime}} n_{c,0}^{2} \right) \right\} = \exp \left( - \left( \sum_{i} s_{i} \right)^{2} \left( \frac{B^{\prime}}{2\pi c_{c}L} \right) \right) .$$

Collecting the results above, we conclude

$$\langle \psi_{s,k=0} | \exp \left( \sum_{i} s_{i} \middle/ \sqrt{c} \right) \rangle = \exp \left( - \left( \sum_{i} s_{i} \right)^{2} \left( \frac{1}{\rho \eta} + \rho \eta \left( A^{\prime} \right)^{2} + \left( B^{\prime} \right)^{2} \frac{2K_{c}^{\prime}}{\pi c_{c}L} \right) \right) .$$
[57] We remark that the figure of the joint distributions presented in the previous report in Ref.[52] contained a small error coming from the error in theirnumerical evaluations. Fig.4 corrects the mistake. This does not change any qualitative conclusions drawn in the previous work.
