IKKβ regulates essential functions of the vascular endothelium through kinase-dependent and -independent pathways

Noboru Ashida¹, Sucharita SenBanerjee¹†, Shohto Kodama²†, Shi Yin Foo¹,³, Matthew Coggins¹, Joel A. Spencer⁴, Parisa Zamiri⁵†, Dongxiao Shen⁶, Ling Li⁷, Tracey Sciuto⁶, Ann Dvorak⁶, Robert E. Gerszten¹,⁵, Charles P. Lin⁴, Michael Karin⁷ & Anthony Rosenzweig¹

Vascular endothelium provides a selective barrier between the blood and tissues, participates in wound healing and angiogenesis, and regulates tissue recruitment of inflammatory cells. Nuclear factor (NF)-κB transcription factors are pivotal regulators of survival and inflammation, and have been suggested as potential therapeutic targets in cancer and inflammatory diseases. Here we show that mice lacking IKKβ, the primary kinase mediating NF-κB activation, are smaller than littermates and born at less than the expected Mendelian frequency in association with hypotrophic and hypovascular placentae. IKKβ-deleted endothelium manifests increased vascular permeability and reduced migration. Surprisingly, we find that these defects result from loss of kinase-independent effects of IKKβ on activation of the serine-threonine kinase, Akt. Together, these data demonstrate essential roles for IKKβ in regulating endothelial permeability and migration, as well as an unanticipated connection between IKKβ and Akt signalling.
Nuclear factor (NF)-κB transcription factors (p65 or RelA, p50, p52, c-Rel, and RelB) generally exist as homo- or heterodimers in the cytosol bound to one of three inhibitory, IκB, subunits (reviewed in ref. 1). In response to a wide variety of stimuli, NF-κB is classically activated through serine phosphorylation and degradation of IκB via the ubiquitin pathway, followed by translocation of NF-κB to the nucleus where it activates transcription. Serine phosphorylation of IκB is mediated by a large multi-unit complex containing two catalytic subunits (1 kappa B kinase (IKK)α and IKKβ)\(^1\), as well as the regulatory subunit IκKγ or NEMO\(^2\). IKKα has an important role in skin development independent of its kinase activity\(^3\) as well as a specialized role in the alternative pathway of NF-κB activation that induces specific genes in B cells via NF-κB2 and RelB\(^4\). IKKβ appears to be the primary kinase mediating phosphorylation of IκB in most cell types and germline deletion of IKKβ results in embryonic lethality due to massive liver apoptosis\(^5\).

In vascular endothelium, NF-κB activation is seen in a wide variety of diseases ranging from atherosclerosis\(^6\) to cancer\(^7\). In addition to a role in endothelial inflammation, previous work has suggested a role for NF-κB in other essential endothelial functions. Pharmacological inhibition of NF-κB decreases vascular permeability\(^8\), although a recent report, using Tie2-driven transgenic overexpression of a superinhibitory IκB-α (sIκB), demonstrated increased vascular permeability after mustard oil stimulation as well as alterations in endothelial tight junctions\(^9\). Tie2-sIκB mice were born at the expected frequency and developed normally despite endothelial NF-κB inhibition\(^10\). A role in endothelial migration has not been reported, although IKKβ deletion promotes migration of embryonic fibroblasts\(^11\).

To better delineate the role of IKKβ in mammalian endothelium in vivo, we used conditional inactivation to generate endothelial-specific IKKβ-deleted mice. These studies show essential roles for IKKβ in the developing placental and adult somatic vasculature, including regulation of endothelial apoptosis and migration, vascular permeability, and vasculogenesis. Surprisingly, although some of these effects (such as apoptosis) result from loss of IKKβ kinase-dependent activation of NF-κB, others (such as permeability and migration) reflect loss of kinase-independent IKKβ modulation, the serine/threonine kinase, Akt. Together, these data demonstrate distinct kinase-dependent and -independent roles for IKKβ in regulating endothelial function, as well as an unanticipated connection between IKKβ and Akt signalling.

**Results**

**Generation of endothelial-specific knockout mice.** To produce mice with endothelial deletion of IKKβ (IKKβ\(^\text{EC} \)) , we bred Tie2-Cre transgenic mice with IKKβ\(^\text{fl} / \text{flo} \) mice\(^12\) on an atherosclerosis-prone ApoE-null genetic background. Interestingly, Tie2-Cre\(^1\)- IKKβ\(^\text{fl} / \text{flo} \)-apoE\(^-/-\) mice were born at lower than the expected Mendelian frequency (7/48 versus 24/48 expected, \(P<0.0001\) by chi-square analysis) raising the possibility of prenatal mortality and were ~25% smaller than Cre-negative littermates at 8 and 32 weeks (Fig. 1a, \(P<0.005\) in repeated two-way ANOVA) in contrast to previously published results with Tie2-sIκB mice\(^9\). Collection of embryos after timed pregnancies revealed that 4/14 (29%) of the Tie2-Cre\(^1\)-IKKβ\(^\text{fl} / \text{flo} \) embryos on either an apoE\(^-/-\) or apoE\(^-/-\) background were dead at E14–16 without evident gross malformation of major organs or vascular structures (Fig. 1b) compared with no fetal loss of the Tie2-Cre-negative IKKβ\(^\text{fl} / \text{flo} \) embryos. Interestingly, placenta from embryos with endothelial IKKβ deletion were hypomorph with fewer blood vessels (Fig. 1c,d).

**Intact vascular endothelium with altered function.** Intact vascular endothelium without detectable endothelial IKKβ expression in IKKβ\(^\text{EC} \) mice was demonstrated in confocal immunohistochemistry (Fig. 1e) and immunoperoxidase staining (Supplementary Fig. S1a) of mice after birth. Electron microscopy confirmed the presence of normal-appearing vascular endothelium, and, in contrast to results with transgenic overexpression of sIκB\(^9\), normal-appearing endothelial tight junctions (Supplementary Fig. S1b–e). To examine the structure and function of IKKβ\(^\text{EC} \) microvessels in vivo, we utilized in vivo microscopy of ear vessels after intravenous injection of Evans blue dye, which binds serum albumen (Fig. 2a; Supplementary Movie 1). Whereas vessel number and branching pattern appeared generally normal, dye rapidly extravasated in the endothelial IKKβ-knockout mice, indicating an increase in baseline vascular permeability even more severe than that seen in Tie2-sIκB mice\(^9\), as it occurred in the absence of stimulation and contrary to the reduced permeability reported with pharmacological NF-κB inhibition\(^5\).

Another important function of vascular endothelium is cellular migration, which has a role in wound healing and angiogenesis. We measured the ability of IKKβ-deficient endothelial cells to migrate in response to the endothelial-specific stimulus, vascular endothelial growth factor (VEGF), in vitro. Endothelial cells from IKKβ\(^\text{fl} / \text{flo} \) mice were infected with a Cre-expressing adenovirus, which effectively mediated deletion of IKKβ and inhibited NF-κB activation without affecting IKKα or -γ (Supplementary Fig. S2). Surprisingly, although IKKβ deletion enhanced fibroblast migration\(^1\), Cre-mediated deletion of IKKβ in endothelial cells cultured from IKKβ\(^\text{fl} / \text{flo} \) mice reduced chemotactic migration to VEGF (Fig. 2b) and migration in a scratch wound-healing assay (Fig. 2c), suggesting a cell-specific role of IKKβ in regulating cell migration. Deletion of endothelial IKKβ in vivo also recapitulated the increased permeability observed in vivo (Fig. 2d). Co-infection of endothelial cells with a recombinant adenovirus encoding wild-type IKKβ, but not a reporter construct, largely restored endothelial migration and reduced permeability to normal (Fig. 2b–d) demonstrating the specificity of this effect. Surprisingly, however, a kinase-inactive mutant of IKKβ (KD-IKKβ), which we had previously shown inhibits endothelial NF-κB activation\(^13\), also rescued these phenotypes with equal efficacy, suggesting they were not due to loss of kinase activity in the IKKβ null cells. Kinase assays confirmed that the wild-type IKKβ construct increased basal IKKβ kinase activity, which was further increased by cytokine stimulation (Supplementary Fig. S3). In contrast, the KD-IKKβ construct did not manifest IKKβ kinase activity at baseline or in response to IL-1 stimulation (Supplementary Fig. S3).

Because NF-κB modulates cell survival through a variety of anti-apoptotic mechanisms\(^1\), we examined the effects of IKKβ deletion on apoptosis in endothelial cells. IKKβ deletion did not affect apoptosis in endothelial cells in the presence of serum but did result in a significant increase in apoptotic endothelial cells after serum deprivation (Fig. 3). Expression of wild type (WT), but not KD IKKβ in IKKβ-deleted endothelial cells, mitigated serum starvation-induced apoptosis in endothelial cells (Fig. 3). This result suggests that IKKβ has both kinase-independent and -dependent effects on important phenotypes of endothelial cells, and reinforces the specificity of results above for migration and permeability.

**Altered Akt signalling.** The abnormal growth and development as well as the severe vascular leakage seen in IKKβ\(^\text{EC} \) contrasted with results reported with endothelial NF-κB inhibition in Tie2-sIκB transgenics\(^9\), despite use of the same promoter. These differences in combination with kinase-independent rescue in vitro raised the possibility that IKKβ modulates baseline endothelial function through NF-κB-independent signalling pathways. Indeed, features of the IKKβ\(^\text{EC} \) mice were reminiscent of those seen in Akt1 null mice, including increased vascular permeability\(^14\) and decreased endothelial migration ex vivo\(^14\)–\(^16\), as well as prenatal mortality, hypotrophic and hypovascular placenta, and small size (thought in
Akt1-null mice to reflect reduced Akt1-eNOS signalling in placental vascular endothelium\textsuperscript{16}). These similarities and previous reports that IKK isoforms (including IKK\textbeta\textsuperscript{17,18}) could physically interact with Akt prompted us to examine Akt in IKK\textbeta\textsuperscript{∆EC} mice. Interestingly, phospho-Akt was markedly reduced in vascular endothelium from IKK\textbeta\textsuperscript{∆EC} mice (Fig. 4a). Similarly, \textit{ex vivo} deletion of IKK\textbeta in endothelial cells resulted in reduced phosphorylation of Akt in response to insulin-like growth factor (IGF)-I (Fig. 4b). A similar blunted response to insulin was seen in IKK\textbeta-deleted endothelial cells \textit{in vitro} (Supplementary Fig. S4). Phosphorylation of GSK3\beta in response to insulin was also blunted in IKK\textbeta-deleted endothelial cells, consistent with inhibition of Akt downstream signalling (Supplementary Fig. S5). Conversely, overexpression of either WT or kinase-inactive IKK\textbeta \textit{in vitro} was sufficient to increase Akt phosphorylation in endothelial cells (Fig. 4c), consistent with a kinase-independent effect of IKK\textbeta on Akt signalling. Previous reports suggested that Akt and IKK\textbeta physically interact in other cell types\textsuperscript{18}. However, we did not find consistent evidence of robust IKK\textbeta-Akt interaction despite multiple immunoprecipitation, GST-pull down and yeast interaction assays.

**Disrupted Akt trafficking.** In response to growth factor stimulation, increased phosphatidylinositol (3,4,5)-trisphosphate (PIP3) binds the pleckstrin homology domain of Akt and prompts its translocation to the cell membrane, where it is localized in caveolar lipid rafts and phosphorylated, and subsequently moves to the nucleus\textsuperscript{19}. Trafficking to lipid rafts has an important role in Akt activation\textsuperscript{20}, and nuclear translocation enhances its anti-apoptotic effects\textsuperscript{21}. IKK\textbeta has also been reported to localize to lipid rafts\textsuperscript{22}. To examine which step in the activation of Akt is affected by IKK\textbeta deletion, we examined intracellular Akt trafficking after stimulation with IGF-I in murine endothelial cells \textit{in vitro}. As previously described\textsuperscript{19}, IGF-I stimulation of control cells induced early localization of Akt to the membrane (evident at 5 min) followed by movement...
to the nucleus (at 15 min) evident by confocal immunohistochemistry (Supplementary Fig. S6a). Subcellular localization of phosphorylated Akt followed a similar pattern (Supplementary Fig. S6b). In contrast, in endothelial cells in which IKKβ had been deleted, IGF-I-induced movement of both total and phospho-Akt to the cell membrane at 5 min and to the nucleus at 15 min were markedly inhibited (Supplementary Fig. S6a and b). Separation of membrane compartments on a sucrose gradient further documented that IKKβ deletion reduced Akt in membrane lipid raft fractions after IGF-I stimulation (Fig. 4d). Similarly, subsequent translocation of Akt to the nucleus after IGF-I treatment was inhibited by IKKβ deletion (Supplementary Fig. S6c). Importantly, endothelial caveolae are present in IKKβΔEC mice and appear normal by electron microscopy (Supplementary Fig. S1b–e), suggesting the observed changes

Figure 2 | Permeability and migration in IKKβ-manipulated endothelial cells in vivo and in vitro. (a) In vivo microscopy images of ear microvessels after injection of Evans blue dye. Representative image at 10 min (top) and cumulative data±s.e. from three independent experiments (bottom) are shown (*P<0.005 in repeated two-way ANOVA). Scale bars: 100µm. See also Supplementary Movie 1 online. (b) In vitro migration to VEGF of endothelial cells in which IKKβ is deleted or WT/−IKKβ is expressed. Cumulative data±s.e. from four independent experiments are shown. Grey bars: VEGF (−), black bars: VEGF (+). *P<0.05 in two-sided Student’s t-test. (c) Wound-healing assay. in trafficking are not due to disruption of caveolae. Expression of either WT- or KD-IKKβ restored Akt trafficking to lipid rafts (Fig. 4e), consistent with the functional rescue of permeability and migration mediated by these constructs. Taken together, these data suggest that IKKβ deletion impairs Akt trafficking and subsequent activation and that the ability of IKKβ to enhance Akt localization to lipid rafts does not require IKK kinase activity.

Akt rescues altered migration and permeability. We tested the functional relevance of IKKβ’s modulation of Akt activation in vitro. Of note, Chen et al. previously demonstrated that permeability in Akt1-deficient endothelial cells is increased in a similar in vitro assay. As noted above, Cre-mediated deletion of IKKβ increased endothelial permeability and expression of either WT or KD IKKβ, which both restore Akt trafficking (Fig. 4e) and increase Akt phosphorylation (Fig. 4c), reduced endothelial permeability (Fig. 2d). Expression of activated Akt (myr-Akt) also restored permeability to normal in IKKβ-deleted endothelial cells (Fig. 4f). Similarly, expression of activated Akt (as well as either WT or KD IKKβ, Fig. 2b,c) restored the ability of IKKβ-deleted endothelial cells to migrate in response to VEGF (Fig. 4g) and in a scratch wound-healing assay (Fig. 2c) in vitro. Together, these data suggest that deletion of IKKβ alters endothelial phenotype at least in part through kinase-independent regulation of Akt activation.

Altered PTEN activity. In the absence of evidence supporting a robust physical interaction between IKKβ and Akt, we examined the PTEN phosphatase, which cleaves PI(3,4,5)P3, removing the primary stimulus for Akt translocation. Inhibitory phosphorylation of PTEN was significantly decreased by IKKβ deletion in endothelial cells, and conversely, overexpression of KD- or WT-IKKβ increased PTEN phosphorylation (Fig. 5a–c). These changes would be expected to increase PTEN phosphatase activity (and decrease Akt translocation/phosphorylation) after IKKβ deletion, and decrease PTEN phosphatase activity in a kinase-independent manner with overexpression. Direct measurement of PTEN phosphatase activity (Fig. 5d) confirmed that this was indeed the case. Taken together, these data implicate PTEN as a mediator of cross-talk between IKKβ and Akt, most likely through effects on the well-described pathway of PI(3,4,5)P3-induced Akt membrane localization.

Impaired ischemia-induced vasculogenesis. The defect in VEGF-induced endothelial migration seen in vitro after IKKβ deletion raised the possibility that endothelial IKKβ would be important in vasculogenesis or the formation of new blood vessels in adults. Given the small number of homozygous IKKβ−/− mice available for study, we addressed this question in heterozygous IKKβ0/− mice. After ligation of the common femoral artery, return of collateral flow was markedly impaired in heterozygous IKKβ0/− mice (Fig. 6). These data are consistent with our in vitro observations and underscore the potential pathophysiological importance of endothelial IKKβ in vasculogenesis due to ischemia or potentially other stimuli.

Discussion

To better delineate the role of IKKβ in mammalian endothelium, we used conditional inactivation to generate mice with endothelial-specific inactivation of IKKβ (IKKβ0/−). Gestational loss of IKKβ0/− embryos and stunted growth probably resulted from hypomorphic placenta. Late stage embryos and surviving adult animals demonstrated an intact somatic vasculature with surprisingly normal morphology. Loss of IKKβ blocked endothelial NF-κB activation. Whereas endothelial apoptosis was not increased at baseline, IKKβ-deleted endothelial cells were more susceptible to serum deprivation-induced apoptosis in vitro and apoptosis was mitigated by expression of wild-type but not kinase-inactive IKKβ. Adult animals lacking endothelial IKKβ manifest increased vascular permeability and impaired vasculogenesis in response to ischemia. In vitro, IKKβ-deleted endothelial cells also demonstrated increased permeability and reduced migration. Surprisingly, these defects were rescued equally well by wild-type and kinase-inactive IKKβ and appear related to kinase-independent activation by IKKβ of the serine/threonine kinase, Akt. Taken together, these data establish an important physiological role for IKKβ in regulating a variety of endothelial functions in mammals, and show unanticipated kinase-independent effects of IKKβ mediating cross-talk with Akt signalling.

The increased vascular permeability seen in vivo in IKKβ0/− mice, is more severe than that seen with either isolated Akt1 deletion or transgenic endothelial NF-κB inhibition, probably reflecting the combined effects of endothelial inhibition of both Akt and IKKβ-NF-κB signalling. This inference is reinforced by the complex relationship of Akt signalling to endothelial permeability. Although Chen et al. found increased permeability in Akt1−/− endothelium both in vivo and in an in vitro model similar to the one used here, Ackah et al. found reduced vascular permeability in Akt1−/− mice in response to VEGF. These differences may reflect technical aspects of the assays used and/or the time-points examined. In addition, the IKKβ0/− mice studied here differ from the Akt1−/− mice not only in the primary and concomitant loss of endothelial IKKβ signalling but also in that Akt signalling is preserved in non-endothelial cells, which may be an important source of a variety of factors affecting vascular permeability including VEGF and angiopoietins.

Our data document cross-talk between two central signalling molecules, IKKβ and Akt, in endothelial cells in vitro and in vivo that appears mediated via the phosphatase, PTEN. Our results differ from previous reports in important respects. First, although
we do find evidence of a signalling connection similar to that described previously, here we find that Akt lies downstream of I KKβ (rather than the reverse), and the two molecules work together to exert important effects on baseline endothelial function. In addition, although it is difficult to completely exclude physical interaction as a contributor to these effects, our data suggest that PTEN has an important role as an intermediary. It is not clear precise molecular mechanism by which IKKβ modulates PTEN activity.

In contrast to our results, several studies in other tissues have reported that IKKβ activation can inhibit insulin signalling in general and Akt in particular. These differences may reflect tissue specific roles of IKKβ, similar to the skin-specific effects revealed by IKKα deletion. However, even in other tissues, IKKβ-induced inhibition of Akt signalling was most pronounced in chronic

Figure 4 | Akt phosphorylation and localization in IKKβ-manipulated endothelial cells in vivo and in vitro. (a) Confocal microscopy images of endothelial cells in IKKβαβ mice immunostained with antibody for CD146 and pAkt. Scale bar: 20 µm. (b) Representative immunoblots for pAkt and Akt in IKKβ-deleted endothelial cells treated with/without IGF-I and its cumulative quantitative densitometry data± s.d. from three independent experiments (*P<0.05 in two-sided Student’s t-test). (c) Representative immunoblots for pAkt and Akt in endothelial cells overexpressed with WT- or KD-IKKβ and its cumulative quantitative densitometry data± s.d. from three independent experiments (*P<0.05 in two-sided Student’s t-test). (d) Representative Akt immunoblots of fractions from sucrose gradient centrifugation of IKKβ-deleted endothelial cells treated with/without IGF-I and its cumulative quantitative densitometry data± s.e. from three independent experiments (*P<0.05 in two-sided Student’s t-test). Ganglioside GM1 is marker for lipid raft fractions. (e) Representative Akt immunoblots of fractions from sucrose gradient centrifugation of IKKβ-deleted endothelial cells expressed with either WT- or KD-IKKβ treated with/without IGF-I and its cumulative quantitative densitometry data± s.e. (n = 5 for ΔIKKβ + Ad-GFP; n = 3 for ΔIKKβ + Ad-IKKβ; n = 5 for ΔIKKβ + Ad-KDIKKβ; *P<0.05 in two-sided Student’s t-test). Ganglioside GM1 is marker for lipid raft fractions. (f, g) In vitro permeability (f) and migration to VEGF (g) in endothelial cells in which IKKβ is deleted or myr-Akt is expressed. Gray bars: VEGF (−), black bars: VEGF (+) for (g). Each panel is cumulative data± s.e. from three independent experiments (*P<0.05 in two-sided Student’s t-test).
inflammatory states or tissues with significant basal NF-κB activation. The findings reported here occur in unactivated endothelial cells at baseline. As noted above, we also provide evidence of kinase-dependent effects of IKKβ on important endothelial phenotypes (for example, apoptosis), although not under basal conditions. Thus, it is quite possible that the relative importance of kinase-dependent and -independent IKKβ effects would shift, even in endothelial cells, in an inflammatory milieu. Nevertheless, these results broaden our understanding of the complex interactions of the IKK signalosome and demonstrate that IKKβ has important kinase- and NF-κB-independent effects, similar conceptually to those shown previously for IKKα, in addition to its well-documented kinase-dependent effects.

Most importantly, these data establish an essential role for IKKβ in fundamental endothelial functions including permeability and migration, and demonstrate the pathophysiological relevance of these effects in a model of ischemia-induced neovascularization. These findings and the observed interaction with Akt signalling may complicate efforts to target IKKβ in some diseases such as atherosclerosis but could be advantageous in other settings. For example, recent work suggests sustained endothelial Akt activation is necessary for maintenance of abnormal tumour vasculature.

Figure 5 | PTEN phosphorylation and phosphatase activity in IKKβ-manipulated endothelial cells. (a–c) Representative immunoblots for IKKβ, pPTEN or PTEN in IKKβ-deleted endothelial cells (a) or WT/KD IKKβ expressed endothelial cells (b) and its cumulative quantitative densitometry data ± s.d. from three independent experiments (c) (*P < 0.05 in two-sided Student’s t-test, **P < 0.0005 in two-sided Student’s t-test). (d) Phosphatase activity of PTEN in IKKβ-deleted or WT/KD IKKβ expressed endothelial cells. Cumulative data ± s.d. from four independent experiments are shown (*P < 0.005 in two-sided Student’s t-test, **P < 0.05 in two-sided Student’s t-test).

Figure 6 | Ischemia-induced neovascularization in vivo. Representative images of blood flow after ligation of common femoral artery, and quantified cumulative data ± s.d. from six animals (3 Cre-negative, 3 heterozygous IKKβEC mice. *P < 0.0005 in two-sided Student’s t-test).
As IKKβ is also a potential target for cancer therapy, strategies aimed at decreasing IKKβ expression could provide additional benefit through secondary inhibition of endothelial Akt signalling and potentially through inhibition of angiogenesis. Understanding the role of IKKβ in vascular endothelium and the associated signalling cascades could help guide therapeutic strategies for a variety of conditions marked by endothelial activation and dysfunction.

**Methods**

**Antibodies and reagents.** Antibodies used include monoclonal anti-IKKβ (Upstate), polyclonal anti-IKKβ (H-470, Santa Cruz Biotechnology), anti-CD146 (Chemicon), anti-total and phospho-(Ser473)Akt, total and phospho-(Ser380/Thr382/383)PTEN, anti-phospho-GSK3β (Cell Signaling). Catch & Release Immunoprecipitation kit (Upstate), ApopTag Red Apoptosis detection kit (Chemicon), NE-PER Nuclear and Cytoplasmic Extraction Reagents Kit (Pierce) and Cell Lysis Buffer (Cell Signaling) were used in accordance with the manufacturers’ instructions. Adenoviral vectors encoding WT IKKβ, kinase-defective (KD) IKKβ, myrAkt, EGFP, Cre and LacZ2 have been described previously in detail.21,23

**Animal studies.** All animal studies were performed after institutional approval and in compliance with applicable guidelines for animal experimentation. IKKβ−/− mice were mated with ApoE−/− (Jackson Immunoresearch Laboratories) to generate IKKβ−/−:ApoE−/− mice which were mated with male Tie2-Cre mice to generate ultimately Tie2-Cre−/−IKKβ−/−:ApoE−/− or Tie2-Cre−/−IKKβlox/lox:ApoE−/− mice. As the phenotype appeared identical on the ApoE−/− or background, data from these mice was combined in some studies.

**Immunohistochemistry.** Slides were incubated in 80% acetone (2 min, 4°C) and incubated in 3% hydrogen peroxide for 10 min. After incubation for 60 min, in blocking solution (5% goat serum, 5% donkey serum in tris buffered saline (TBS)), slides were incubated with diluted antibody for pAkt (1:50), polyclonal anti-mouse and rhodamine-conjugated donkey anti-rabbit secondary antibodies (Jackson, 1:100) were applied to the slides for 60 min.

**Immunoperoxidase staining.** Slides were incubated with Avidin Block (Vector Laboratories SP-200, Avidin-Biotin blocking kit) for 15 min before applying Biotin Blocking Kit for 15 min. Diluted rabbit anti-Von Willebrand factor (Chemicon, 1:200) was applied to each slide (4°C, overnight). Diluted biotinylated streptavidin (BD Biosciences, 1:200) was applied to the slides for 60 min. Immunoperoxidase staining was carried out using a DAKO Stain Autostainer System and the reaction was visualized with 3,3′-diaminobenzidine tetrahydrochloride (DAB) followed by counterstaining with hematoxylin.

**In vivo permeability assay.** Vessel permeability was assessed by leakage of the Evans blue dye from the mouse ear vascularity following intravenous injection. An intravenous catheter was inserted into the tail vein of anesthetized mouse before placing the mouse ear onto a stage of a video-rate scanning laser confocal microscope. The ear skin was gently spread onto a coverslip with a drop of 1% methocellose. At the start of each experiment, 100 μl of 2% Evans blue dye was injected via the tail vein. Images were acquired from an appropriate vascular area (at about 50 μm under the surface of the skin) and every 30 s for at least 10 min after injection. Each image was acquired by averaging 30 video frames (1 s integration time) using an Olympus 60×, numerical aperture 1.2, water-immersion objective producing symmetrical pores within a transparent polyethylene membrane.

**In vitro permeability assay.** Vessel permeability was assessed by leakage of the Evans blue dye from the mouse ear vascularity following intravenous injection. An intravenous catheter was inserted into the tail vein of anesthetized mouse before placing the mouse ear onto a stage of a video-rate scanning laser confocal microscope. The ear skin was gently spread onto a coverslip with a drop of 1% methocellose. At the start of each experiment, 100 μl of 2% Evans blue dye was injected via the tail vein. Images were acquired from an appropriate vascular area (at about 50 μm under the surface of the skin) and every 30 s for at least 10 min after injection. Each image was acquired by averaging 30 video frames (1 s integration time) using an Olympus 60×, numerical aperture 1.2, water-immersion objective producing symmetrical pores within a transparent polyethylene membrane.

**ENDOTHELIAL CELL CULTURE.** Lungs of IKKβ−/− mice were harvested, minced finely and digested in 25 ml collagenase (Roche, 2 mg ml−1). Cells were incubated with anti-P-ECAM-1 antibody (BD Biosciences, 1:100) and cells bound with antibody were isolated magnetically with mouse anti-rat kappa microbead (Miltenyi Biotec), washed with complete media (DMEM, 20% FCS, 0.1 mg ml−1 heparin, 0.1 mg ml−1 endothelial cell mitogen (Biomedical Technologies), nonessential amino acids, sodium pyruvate, l-glutamine and penicillin/streptomycin at standard concentrations) and cultured in fibronectin-coated, tissue-culture flasks. Nonadherent cells were removed after 24 h and media replaced. At confluence, endothelial cells were magnetically selected further using anti-ICAM-2 antibody (BD Biosciences, 1:100).

**Wound-healing assay.** Confluent endothelial monolayers in 6 dishes were scraped with sterilized 1 ml micropipette tips to create a cell-free zone. Microscopic images were captured at 0, 30, 60, 120 and 180 h, and the percentage of the cleared area was quantified using Image J software (National Institutes of Health, USA).
