Abstract

Background: We studied the association between iron intake and polymorphisms in the iron transporter gene, SLC40A1, and the risk of tuberculosis.

Methods: We compared iron intake, the frequency of SLC40A1 mutations, and interactions between these variables among 98 TB patients and 125 controls in Kwazulu-Natal, South Africa.

Results: Four SLC40A1 SNPs were associated with an increased risk of tuberculosis and one with reduced risk. We also found a gene-environment interaction for four non-exonic SNPs and iron intake.

Conclusions: This pilot study demonstrated an association between polymorphisms in SLC40A1 and tuberculosis and provided evidence for an interaction between dietary iron and SLC40A1.

Key words: SLC40A1, Ferroportin, FPN1, Tuberculosis, Mycobacterium, Iron, Genetic, Single nucleotide polymorphism (SNP), Gene-environment
One-third of the world’s population is infected with *Mycobacterium tuberculosis* (*MTB*), but only a minority of these develop active tuberculosis. Excess iron has been implicated as a risk factor for TB in both in vitro and clinical studies. Restriction of iron in culture media curtails growth of *MTB*, and iron loading in mice enhances bacterial growth in lung and spleen [2]. Iron supplementation has been shown to lead to increased morbidity and mortality in patients while autopsies show that death from TB can be accompanied by splenic iron overload [3]. Recognizing the physiological importance of iron availability for mycobacterial growth [4], we hypothesized that functional variants of the iron transporter, ferroportin 1 (FPN1), may affect host susceptibility to TB.

“African iron overload syndrome” is characterized by increased iron and serum ferritin, but unlike “classic” HFE hemochromatosis, excess iron is localized in the reticuloendothelial system. Although this syndrome had been ascribed to intake of traditional African beer brewed in non-galvanized steel drums, an autosomal dominant form of iron overload has been described in which iron accumulation is restricted to reticuloendothelial cells [6]; this entity is now believed to be identical to the “ferroportin disease” associated with polymorphisms in *SCL40A1*, the gene which encodes the iron exporter, FPN1 [5].

FPN1 is found on the basolateral surface of enterocytes and macrophage cell wall. The current model posits that dietary iron absorbed by enterocytes is moved into the circulation by FPN1, then circulates bound to transferrin and is delivered to tissues via endocytosis of the iron/transferrin complex. Most of the body’s iron is used for hemoglobin production by erythrocytes, and iron from senescent red blood cells is recovered when macrophages ingest and catabolize these cells. Macrophages transport scavenged iron to bone marrow, where it is released via FPN1. Gain-of-function
mutations in SCL40A1 prevent FPN-1 inactivation by the iron regulatory hormone hepcidin, and cause a classic hemochromatosis phenotype manifested by low macrophage iron, increased transferrin saturation, and hepatocellular iron loading [6]. Loss-of-function variants inhibit the protein from localizing to the cell surface, impairing iron egress and leading to macrophage iron overload [7].

To test the hypothesis that high levels of macrophage iron increase TB risk, we evaluated the gene-environment interactions between SLC40A1 polymorphisms and dietary iron intake and outcome, TB disease.

**Methods**

We conducted this study in Pietermaritzburg in KwaZulu-Natal, South Africa, an area inhabited by the Zulu, a group at high risk for African iron overload syndrome [8, 27]. TB incidence in this community is high at 1,163 per 100,000 compared to overall South Africa incidence of 820 per 100,000 [28]. We enrolled consecutive HIV negative patients over 18 years old in whom pulmonary tuberculosis was confirmed by two consecutive sputum smears positive for acid fast bacilli. Controls were recruited from those who tested HIV negative at Voluntary Counseling and Testing centers and from households of cases. Controls were unrelated to cases, were >18 years old, and had no history or symptoms of TB disease. Covariates included gender, age, race, current smoking status, self-reported diabetes mellitus, current alcohol use, BCG vaccination and socio-economic status. To assess excess iron intake, we evaluated ingestion of home-brewed beer and vitamins. Host DNA was obtained from a saliva sample using the Oragene®DNA sample collection kit (DNA GenotekInc, Kanata, ON, Canada) and was stored at -70°C.
The study was approved by the institutional review board of Harvard School of Public Health, the Biomedical Research Ethics Committee at the University of KwaZulu-Natal, Durban, and the Department of Health, KwaZulu-Natal, South Africa.

**Sequencing of SLC40A1**

To detect new polymorphisms specific to this population, we sequenced the flanking 5’ and 3’ regions, promoter regions, exons, and proximal non-coding regions of the SLC40A1 gene from 28 cases and 18 controls. The primer design used Beckman Coulter Genomics’ Linux-based amplicon design software. Genomic DNA was amplified using Thermo-StartReddyMix PCR Master Mix (ThermoScientific) and 0.2 uM forward and reverse PCR primers. Solid phase reversible immobilization chemistry (AMPure - Beckman Coulter Genomics) and dye-terminator fluorescent sequencing were used to purify the PCR products. Polymorphisms were detected using polyphred 5.04 (University of Washington).

**Genotyping**

We identified thirteen SNPs in the SLC40A1 locus from the International HapMapProject dbSNP and selected 20 of the 41 polymorphisms identified by resequencing, choosing SNPs based on allele frequency > 2%, location in the coding regions, and SNP assay design parameters. SNP genotyping was performed using Sequenom MALDI-TOF primer extension assay using the Sequenom (San Diego, CA) MassARRAY system.

**Statistical Analysis**

Univariate analysis was conducted using logistic regression models in STATA version 10. SNPs were excluded from the analysis if 1) they deviated from Hardy Weinberg equilibrium (P<0.001), 2) ≥25% of the data was missing, or 3) they had a pairwise
threshold of \( r^2 \geq 0.8 \) using linkage disequilibrium based pruning (PLINK 2007). Genotypes were coded using an allelic model, and allele frequency distributions were compared between cases and controls using PLINK. Gene-environment interactions with iron ingestion were assessed using the likelihood-ratio test (LRT) and a case-only analysis for a gene-environment interaction [8]. We considered results significant at the alpha = .05 level.

Results

Population
We identified 104 persons with TB and 127 controls, of whom 100 cases and 126 controls agreed to participate in the study. DNA samples were available from 98 cases and 125 controls.

Host characteristics
We found no association between iron ingestion through home-brewed beer, iron supplements, or multivitamins and TB disease. Factors found to be significantly associated with TB included age (\( p<.001 \)), male sex (\( p=.03 \)), and self-reported diabetes mellitus (\( p=.01 \)).

Sequencing and genotyping
Resequencing identified 41 polymorphisms including 14 novel polymorphisms of which 33 were genotyped and 32 had a genotyping efficiency of >75%.

SNP association analyses
We excluded one SNP which deviated from Hardy-Weinberg equilibrium and seven based on the linkage disequilibrium based pruning procedure. Table 2 shows that among the remaining 24 SNPs, four significantly increased the risk of TB disease (GRCh37 190445284 \( P=0.01 \), 190445194 \( P=0.05 \), 190444943 \( P=0.05 \), 190423785 \( P=0.04 \), while one reduced risk (190442893 \( P=0.03 \)). Three of these SNPs (GRCh37 190445284, 190445194 and 190444943) occurred at low frequency while two (190423785 and 190442893) occurred in at least 25% of the population.

*Gene-environment interactions*

We found a significant gene-environment interaction between each of fours SNPs and iron intake (GRCh37 190452872 LRT \( P=0.02 \), 190446541 LRT \( P=0.004 \), 190432613 LRT \( P=0.02 \), 190423785 LRT \( P=0.05 \); Table 3). Among persons who consumed excess iron, two SNPs were associated with a statistically significant increased risk of TB disease, GRCh37 190446541, OR 3.33 (95% CI, 1.31, 8.48) and GRCh37 190423785, OR 3.19 (95% CI, 1.18, 8.61) and a third GRCh37 190452872 manifested an association that was not significant. Among those not exposed to increased iron, GRCh37 190432613 protected against TB disease (OR 0.51 (95% CI, 0.30, 0.87). Three polymorphisms that were excluded by linkage disequilibrium based pruning, were closely associated with polymorphisms with evidence of gene-environment interactions: GRCh37 190452957 with GRCh37 190452872; and GRCh37 190428248 and 190425474 with GRCh37 190432613.

Of note, although GRCh37 190430096, causing the amino acid substitution Q248H, was not found to be associated with TB disease, the OR among participants with iron exposure was 0.13 (95% CI, 0.01, 2.49) compared to 1.15 (95% CI, 0.55, 2.41) in those without.
Discussion

Multiple lines of evidence suggest that host iron status influences both the occurrence and outcomes of tuberculosis. Here, we assessed the association between polymorphisms in the gene SLC40A1 and active TB and found an association between TB disease and five polymorphisms within the iron transporter gene associated locus. Furthermore, we found preliminary evidence that iron ingestion through home-brewed beer and vitamin supplements modified the association between TB and four polymorphisms. These data suggest that iron metabolism defects may affect TB susceptibility and raise the possibility of a gene-environment interaction between SLC40A1 and iron intake in modifying the risk of TB.

Mutations in SLC40A1 could affect MTB growth and replication through multiple routes. Some SLC40A1 SNPs alter the efficacy of FPN1 in absorbing iron across the duodenum and in iron export from macrophages [5], changes which may affect mycobacterial iron availability. SLC40A1 mutants also manifest altered levels of pro-inflammatory cytokines including tumor necrosis factor-α and macrophage migration inhibitory factor [9] and FPN1 over-expression has been shown to impair nitric oxide production in MTB infected macrophages [10].

In this study, we identified SNPs associated with TB disease in the promoter, untranslated, intronic and downstream regions of SLC40A1. Transcriptional and translational control of SLC40A1 expression is thought to be tightly regulated by iron, and polymorphisms in non-exonic regions of SLC40A1 may alter such regulation (11). For example, Marro reported that heme upregulates SLC40A1 transcription and that this activation relies on a highly conserved enhancer region in the promoter [12]. Deletion of
the iron responsive element (IRE) in the 5’ UTR region abrogated this effect, suggesting that the IRE confers translational regulation through iron regulatory proteins that bind to the mRNA transcript in low iron states to prevent translation. Alternative promoters and splicing have also led to the loss of an IRE in SLC40A1 transcripts in vivo [13]. Notably, two of the polymorphisms that we found to be associated with TB disease are located in the 5’UTR in proximity to the IRE, raising the possibilities that polymorphisms in the promoter regions may alter transcriptional regulation while those in the untranslated regions may affect the function of the IRE and therefore translational regulation.

Iron ingestion modified the association between TB disease and four SNPs found near the promoter, and in intronic and untranslated regions. This interaction may have resulted from altered iron absorption at the level of the duodenum or impaired iron egress from macrophages in the setting of excess iron intake. Polymorphisms affecting transcription may render SLC40A1 unresponsive to iron regulation through the IRE, which may also lead to macrophage iron overload. We note that the mutation, Q248H has been previously associated with an iron metabolism phenotype in African and African Americans and that affected carriers exhibit elevated ferritin levels, reduced mean corpuscular volumes, elevated C-reactive protein levels, and low levels of tumor necrosis factor and macrophage inhibitory factor [14]. In vitro experiments show that Q248H mutants retain their ability to export iron, and some investigators have speculated that the mutation may produce a variant of FPN1 that is not inhibited by hepcidin and thus functions as a “permanently turned-on iron exporter” [15]. Our finding that Q248H was protective against TB disease among those with increased iron intake, although not statistically significant, is consistent with this phenotype, since carriers would be expected to have low macrophage iron levels even in the presence of excess circulating iron.
This study had multiple limitations. Although we attempted to capture relevant SNPs, we did not sequence the entire gene and may have missed non-exonic polymorphisms associated with TB disease. Since we did not directly measure host iron indices but assessed iron ingestion from vitamin supplements and home-brewed beer, we may have misclassified host iron status. Although previous reports indicate that the iron content of home-brewed beer is 258 fold higher than that found in commercial beer [15], we did not measure the iron content of the beer or systematically account for the frequency of beer intake. Finally, we did not test for the possibility of population stratification; however, we expect that bias would be minimal due to the homogenous study population with common Zulu ancestry.

This candidate gene study was planned as an exploratory pilot study and was not powered to account for multiple testing. However, the fact that 5 of 24 SNPs in the SLC40A1-associated locus were found to be associated with TB disease in a biologically plausible candidate gene suggests that this gene is a good candidate for further study. Future studies should sequence the entire SLC40A1 gene to capture the full range of polymorphisms, include rigorous measurements of iron status and intake, carefully document covariates and be powered to assess potential gene-environment interactions. In addition, studies assessing the molecular mechanisms for the associations between SLC40A1 polymorphisms and TB disease, including measurement and evaluation of SLC40A1 transcripts, would complement the genetic studies and provide further insight into the function of FPN1.
