Abstract.—Well-preserved microfossils occur in abundance through more than 1000 m of lower Mesoproterozoic siliciclastic rocks composing the Roper Group, Northern Territory, Australia. The Roper assemblage includes 34 taxa, five interpreted unambiguously as eukaryotes, nine as possible eukaryotes (including *Blastanosphaira kokkoda* new genus and new species, a budding spheromorph with thin chagrinat walls), eight as possible or probable cyanobacteria, and 12 incertae sedis. Taxonomic richness is highest in inshore facies, and populations interpreted as unambiguous or probable eukaryotes occur most abundantly in coastal and proximal shelf shales. Phylogenetic placement within the Eukarya is difficult, and molecular clock estimates suggest that preserved microfossils may belong, in part or *in toto*, to stem group eukaryotes (forms that diverged before the last common ancestor of extant eukaryotes, or LECA) or stem lineages within major clades of the eukaryotic crown group (after LECA). Despite this, Roper fossils provide direct or inferential evidence for many basic features of eukaryotic biology, including a dynamic cytoskeleton and membrane system that enabled cells to change shape, life cycles that include resting cysts coated by decay-resistant biopolymers, reproduction by budding and binary division, osmotrophy, and simple multicellularity. The diversity, environmental range, and ecological importance of eukaryotes, however, were lower than in later Neoproterozoic and Phanerozoic ecosystems.

Introduction

In classifying the past 541 million years as the Phanerozoic Eon, stratigraphers give formal recognition to the animal fossils commonly found in rocks of this age. In terms of evolution, the age of animals must form the latter part of a phylogenetically broader and historically deeper age of eukaryotes, but when protists emerged as major participants in marine ecosystems remains uncertain. Molecular clocks, calibrated largely by Phanerozoic fossils, nearly all suggest that crown group eukaryotes emerged during the Proterozoic Eon. The error bars are large, but even so, the oldest (ca. 2000 Ma) and youngest (800 Ma or a bit earlier) molecular estimates for the divergence of crown group eukaryotes do not overlap (e.g., Douzery et al., 2004; Hedges et al., 2004; Yoon et al., 2004; Berney and Pawlowski, 2006; Chernikova et al., 2011; Parfrey et al., 2011; Eme et al., 2014). Neither early nor late crown group emergence precludes the possibility of a substantial earlier record of stem group eukaryotes (Javaux et al., 2010; Javaux, 2011; Knoll, 2014; Sugitani et al., 2015; Butterfield, 2015).

Diverse eukaryotic microfossils occur in rocks 800 Ma and younger (Porter et al., 2003; Butterfield, 2004; Butterfield, 2005a, 2005b; Knoll et al., 2006; Cohen and Knoll, 2012), and these include at least a few populations assigned with confidence to extant eukaryotic clades (e.g., Butterfield et al., 1994; Porter et al., 2003). Accepting the ~1100-Ma fossil *Bangiomorpha pubescens* as a red alga (Butterfield, 2000), possibly a stem group rhodophyte (Yang et al., 2016), further

requires that crown group eukaryotes evolved earlier than this. Older microfossils potentially push the eukaryotic crown group still deeper into the past (Moczyłowska et al., 2011; Butterfield, 2015), but only if these fossils can be confidently interpreted not only as eukaryotes but also as crown versus stem group taxa—a potentially challenging distinction in ancient rocks (Knoll, 2014).

Improved understanding of the timing and context of early eukaryotic divergence begins with careful systematic analysis of well-preserved fossil populations drawn from basins characterized by good age and environmental control. One such basin is recorded by the Mesoproterozoic Roper Group, Northern Territory, Australia. Abundant microfossils were discovered in coastal marine mudstones of the McMinn Formation, near the top of the group (Peat et al., 1978). Our investigations reveal that fossils are abundant and exceptionally well preserved throughout the Roper succession, enabling us to document the paleoenvironmental as well as stratigraphic distribution of microfossil assemblages (Javaux et al., 2001).

Geologic setting

The Roper Group is a ramp-like sedimentary succession developed in association with regional rifting following an episode of late Paleoproterozoic tectonism known locally as the Isan Orogeny (Betts and Gilles, 2006; de Vries et al., 2008). Although limited Roper outcrop is dominated by erosionally resistant sandstone units, an extensive and lithologically

heterogeneous record of Roper deposition is available in drill core obtained during the 1970s and 1980s. The >1800 m Roper succession consists almost entirely of siliciclastic rocks divided by Abbott and Sweet (2000) into half a dozen third-order sedimentary sequences. Environments recorded in each sequence range from basinal black shales deposited below storm wave base during maximum flooding to paralic and even fluviatile sandstones, as well as oolitic ironstones found as a marginal-marine facies in highstand systems tracts. Depositional age is constrained by a U-Pb zircon age of 1492 ± 4 Ma for a tuff in the Mainoru Formation, low in the Roper succession (Jackson et al., 1999), Re-Os shale dates of 1417 ± 29 Ma and 1361 ± 21 Ma for the Velkerri Formation in the upper part of the succession (Kendall et al., 2009), and a less reliable, but broadly consistent Rb-Sr illite date of 1429 ± 31 Ma for shale within the McMinn Formation, near the top of the group (Kralick, 1982). Thus, Roper deposition took place about 1500–1400 Ma (Figure 1).

Surface waters in the Roper seaway were oxic, as determined by iron-speciation chemistry (Shen et al., 2003), but several lines of evidence indicate that within the Roper basin the oxygen minimum zone was commonly anoxic and ferruginous, and at times euxinic (Shen et al., 2003; Planavsky et al., 2011). Consistent with this, S isotopic data document an active microbial sulfur cycle (Shen et al., 2003; Johnston et al., 2008), with facies-specific differences in expressed fractionation suggesting that bacterial sulfate reduction occurred in the water column in basinal environments, but was confined to sediments in coastal settings (Shen et al., 2003). Mo abundance and isotope values for Roper samples point more broadly to early Mesoproterozoic oceans with widespread subsurface anoxia, including sulfidic water masses more extensive than today (Arnold et al., 2004; Kendall et al., 2009), with some exceptions locally (Sperling et al., 2014).

Materials and methods

Carbonaceous shales occur throughout the Roper succession in environmental settings that range from basinal to lagoonal (Abbott and Sweet, 2000; Javaux et al., 2001). A majority of these shales contain microfossils preserved as organic compressions, and in a subset of these, distributed throughout the succession, preservation is excellent. The fossils described here come from the following cores: Amoco (A) 82-3 and Golden Grove (GG) 1, repositated at the Northern Territory Geological Survey in Darwin, and Urupunga (U) cores 4, 5, and 6, repositated at the Australian Geological Survey Organization, Canberra. Collectively, these cores represent most of the Roper Group, save for the upper McMinn and Chambers River formations at the top of the succession.

All microfossils come from residues of static acid maceration and have been examined with transmitted light microscopy. For some taxa, detailed morphological observations with SEM, wall ultrastructure with TEM, and wall microchemistry are described elsewhere (Javaux et al., 2003, 2004; Marshall et al., 2005). Systematic description is focused on the genus and species levels, with taxa ordered alphabetically, and the International Code of Nomenclature for Algae, Fungi, and Plants is followed. Sample number includes core number and depth (e.g., U6 230.8 m is sample from core Urupunga 6 at 230.8 m depth).

Repositories and institutional abbreviations.—All illustrated specimens are repositated in the Paleobotanical Collections of Harvard University (HU numbers).

Systematic paleontology

Classification of Roper microfossils presents challenges at either end of the Linnean hierarchy, in both cases reflecting the limited availability of systematically useful characters and character states. At the fine scale, the challenge is to recognize discrete populations and classify them in light of previously diagnosed taxa. Populations can be demarcated in terms of general form (e.g., spheroidal versus cylindrical), size frequency distribution, surface ornamentation when present, and wall thickness and textures (when obvious ornamentation is absent).

Preliminary research shows that morphologically simple Mesoproterozoic microfossils can also preserve distinct wall ultrastructures (Javaux et al., 2004), but extensive TEM imaging would be prohibitive, and existing diagnoses do not take ultrastructural characters into account. Because of character limitations and the ways that observed traits have been used in classification, it can be easier to recognize populations as distinct than it is to assign them to formal taxa, especially for the abundant but simple spheroidal vesicles known as leiosphaerids. We recognize 34 distinct entities within the Roper assemblage.

The other systematic challenge is to relate Roper populations to higher taxa, which can be problematic even at the level of domain. For this reason, we find it useful to provide qualitative confidence estimates for phylogenetic interpretation—with what degree of certainty we recognize a given population as eukaryotic or bacterial. We show that five morphospecies can be classified with confidence as eukaryotes, including three distinct populations of ornamented spheromorph acritarchs (*Dictyosphaera delicata*, *Satka favosa*, and *Valeria lophostriata*), one acanthomorph acritarch (*Tappania plana*), and one population of large striated tubes (*Lineaforma elongata*). Nine additional taxa are considered possible eukaryotes (six smooth-walled spheromorphs: *Leiosphaeridia crassa*, *L. jacutica*, *L. minutissima*, *L. tenuissima*, *Leiosphaeridia* sp., and *L. ternata*; one spheromorph population with a granular wall texture (*L. atava*), and two populations of budding spheromorphs (cf., *Gemuloides doncookii* and *Blastanosphaera kokkoda*). Eight taxa of filaments (*Palaeolyngbya catenata*, five species of *Siphonophycus*, *Trachytrichoides* sp.) and vesicles with rounded bulges inferred to be imprints of internal cells (*Squamosphaera colonialica*), are interpreted as probable cyanobacteria, whereas 12 distinctive populations can be classified only as incertae sedis; this group includes five types of spheromorphs (Unnamed forms B to E), six colonial forms (*Chlorogloeopsis contexta*, cf. *Coneosphaera arctica*, *Eomicrocystis magilca*, *Synsphaeridium* spp., *Symplastosphaeridium* spp., and a large compartmentalized multicellular form—unnamed form A), and two filamentous taxa (*Tortunema* sp. and unnamed form F). Some of the Roper colonial and filamentous microfossils are interpreted as probable cyanobacteria because of both their occurrence in shallow-water photic zone and their morphology.

Figure 1. The Roper Group, showing location, facies distribution and stratigraphic column (modified from Javaux et al., 2001).

Genus *Blastanosphaera* new genus

Type species.—*Blastanosphaera kokkoda*, by monotypy

Diagnosis.—As for type species.

Etymology.—From the greek βλαστᾶω, to bud or to germinate, σφαῖρα, sphere, and κοκκῶδη, granular.

Blastanosphaera kokkoda new species

Figure 2.1–2.11

Holotype.—Specimen Figure 2.1, palynological slide U5 569.1 m, England finder coordinates R/S42, from the Wood Duck Member of the Mainoru Formation, Roper Group.

Diagnosis.—Spheromorph, a few up to ~100 μm in diameter, with very thin chaggrinate wall, small sinuous folds, and one lanceolate fold predominantly near the margins of compressed vesicles. Division by budding, with one or several large spherical scars left by detaching buds; serial budding without cells detaching common, leading to a colonial habit. Commonly, taphonomic alteration results in the thin wall peeling off the vesicle from an equally tenuous internal layer.

Occurrence.—Mesoproterozoic, Wood Duck Member of the Mainoru Formation, Roper Group, Australia.

Description.—Spheromorph with very thin chaggrinate wall and small sinuous folds, and one lanceolate fold predominantly near the margins of compressed vesicles. Size 3–93 μm in minimum diameter (mean: 28.7 μm, $\sigma = 16.8 \mu\text{m}$, $N = 149$). Two specimens oval shaped (52–104 μm long and 32–64 μm wide), and one specimen (27 μm in diameter) bears an elongate expansion (40 μm long x 8 μm wide) (Fig. 2.3). Division by budding, with cells staying attached and forming irregular colonies, cells rarely isolated, often attached to one to four other cells, commonly with large spherical scars left by detaching buds or adjacent cells. Range of diameter and morphology may vary greatly, from spherical to oval to filamentous. Commonly, taphonomic alteration results in the thin wall peeling off the vesicle from an equally tenuous internal layer.

Materials.—149 specimens measured, as clustered populations in basal facies (samples U5 581.9 m and 569.1 m in the Wood Duck Member of the Mainoru Formation).

Remarks.—The Roper population forms an essentially monospecific assemblage in euxinic basal shales, and is rare in other facies. It differs from *Gemmuloides* by the thin chaggrinated wall, circular scars, and multiple attached buds forming colonies. It also differs from *Eosaccharomyces ramosus* Hermann, another

budding spheromorph forming colonies, by the chaggrinate ornamentation of the vesicle wall, and taphonomic features such as circular scars (Fig. 2.4) and one large lanceolate fold at periphery and very thin folds more centrally distributed (Fig. 2.1, 2.10). The attachment to a biofilm reported and illustrated by Hermann (1990, pl. 14) and Hermann and Podkovyrov (2012) is not observed for the Roper population, although it is not mentioned as a diagnostic character (Jankauskas et al., 1989). Growth of oval cells oriented in the direction of the “branches” of the colony do occur in the Lakhanda material, as underscored by Knoll et al. (2006), but this is not always the case (see Hermann 1990, pl. 14, figs. 5, 7), and is not reported as a diagnostic criterion in Jankauskas et al. (1989). The chaggrinate spheromorphs commonly show evidence of budding (Fig. 2.2–2.8), forming spheres (Fig. 2.6–2.8) or elongate extensions (Fig. 2.3), with up to seven specimens attached. Some specimens bear a distinct circular hole rimmed by a fold in the wall (with a diameter up to more than 60% of the vesicle diameter) (Fig. 2.4). Because budding specimens may bear this hole (Fig. 2.7), it cannot be interpreted as a pylome (excystment structure), but rather as a scar left when connected individuals detached. Commonly, the thin wall has partially peeled off, exposing the lighter inner side of the vesicle wall (Fig. 2.6). Cells can be isolated, or more commonly attached to 1 to 4 other cells (Fig. 2.7). *Blastanosphaera kokkoda* differs also from other spheromorphs with chaggrinate walls, such as *L. obsuleta* and *L. atava*, by its prominent budding habit and consequent colonial association, very thin wall, and circular scars.

The chaggrinate appearance seems to be an ornamentation rather than taphonomic alteration, suggesting eukaryotic affinity. SEM shows a granular wall and occasional taphonomic holes (Fig. 2.11). Budding is also consistent with eukaryotic affinities, resembling yeast behavior, but detailed ultrastructural and microchemical analyses will be required to confirm the affinity of this population. Due to its budding without cells detaching and forming colonies, *E. ramosus* has been interpreted as a possible fungus (yeast-like) by Hermann and Podkovyrov (2012) or as social amoebae, although these are difficult to preserve as compressions (Porter, 2006), except in stages of their life cycle when they can produce cellulose walls. Interestingly, cells of the modern yeast *Saccharomyces* may bear several circular scars, and when budding rapidly, form pseudomycelia. However, budding as a form of asexual reproduction also occurs in some bacteria (cyanobacteria, prothecate proteobacteria; Angert, 2005), in addition to some protists, fungi (yeast), and animals. The chaggrinate ornamentation of the wall combined with large size suggest the Roper fossils are probable eukaryotes, and their common budding and pseudocolonial habit shows they represent metabolically active, reproducing vegetative cells. Their restricted distribution in deeper anoxic facies may suggest an anaerobic metabolism (see Muller et al., 2012 for a review of modern anaerobic eukaryotes)

Figure 2. Photographs of Roper organic-walled microfossils: (1–11) *Blastanosphaera kokkoda* n. gen. n. sp.; (2) specimen starting budding; (3) specimen showing an elongate expansion; (4) specimen showing circular opening; (6) the bottom specimen's wall is peeling off the vesicle; (8) thick folds between attached specimens; (5–8) specimens showing multiple budding; (11) SEM picture showing details of granular wall. or facultatively aerobic metabolism at low oxygen tensions. Alternatively, they could have been planktonic, but in this case, their limitation to deeper anoxic facies is difficult to explain.

Genus *Chlorogloeaopsis* Maithy, 1975, emend. Hofmann and Jackson, 1994

Type species.—*Chlorogloeaopsis zairensis* Maithy, 1975, from the Bushimay (now Mbuyi-Mayi) Supergroup, RDC, Meso-Neoproterozoic.

Other species.—*Chlorogloeaopsis kanshiensis* (Maithy, 1975), n. comb. Hofmann and Jackson, 1994; *Chlorogloeaopsis contexta* (Hermann, 1976) n. comb. Hofmann and Jackson, 1994.

Chlorogloeaopsis contexta (Hermann in Timofeev, Hermann, and Mikhailova, 1976), emend. Hofmann and Jackson, 1994
Figure 2.12–2.13

1976 *Polysphaeroides contextus* Hermann in Timofeev, Hermann, and Mikhailova, p. 42, pl. 14, fig. 3

1989 *Polysphaeroides contextus*; Jankauskas et al., p. 119, pl. 27, figs. 10a, b

1990 *Polysphaeroides contextus*; Hermann, p. 26, pl. 8, fig. 8

1994 *Chlorogloeaopsis contexta*; (Hermann in Timofeev et al., 1976), emend. Hofmann and Jackson, p. 19, figs. 12.13–12.15

Holotype.—*Polysphaeroides contextus* Hermann, 1976 in Timofeev, Hermann, and Mikhailova, p. 42–43, pl. 14, fig. 3; from the late Riphean (Tonian) Miroedikha Formation of the Turukhan Uplift, Siberia.

Occurrence.—Mesoproterozoic and Neoproterozoic successions worldwide, such as the Mbuyi-Mayi Supergroup, RDC; the Miroedikha Formation of the Turukhan Uplift, Siberia; the Roper Group, Australia; the Bylot Supergroup, Canada.

Description.—One cylindrical colony without envelope, composed of several indistinctly defined rows of cells 3–5 μm wide; colony 400 μm long and 25 μm wide.

Materials.—One specimen from sample U6 240.2 m, Mainoru Formation.

Remarks.—The spelling of the genus was corrected by Hofmann and Jackson (1994, p. 18–19) and simultaneously (both in July 1994) by Butterfield et al. (1994, p. 72). Hofmann and Jackson (1994) recognized three species of *Chlorogloeaopsis*: *C. contexta* (Hermann, 1976) n. comb. Hofmann and Jackson, 1994, has indistinct rows of cells and cell diameter ranging from 1 to 5 μm ; *C. zairensis* Maithy, 1975 with cells 8 to 10 μm in diameter, two to four in a row, while *C. kanshiensis* has cells 10–15 μm in diameter, two or three distinct rows of cells. The Roper population differs from *C. kanshiensis*, defined by two or three rows of cells, and from *Polysphaeroides* spp., which are loose aggregates of spheroidal dispersed cells or pairs, tetrads, octads, and spheroidal colonies of up to 10–20 cells in a sheath.

Genus *Coneosphaera* Luo, 1991

Type species.—*Coneosphaera inaequalalis* Luo, 1991, from the Changlongshan Formation, Neoproterozoic, China.

Other species.—*Coneosphaera artica* Hofmann and Jackson, 1994; *Coneosphaera* sp. Hofmann and Jackson, 1994.

Coneosphaera sp.
Figure 2.14

Description.—50–51 μm thin-walled light brown spheromorphs loosely associated with many smaller 2–4 μm vesicles on the wall surface and close to their periphery. Three specimens observed.

Materials.—Three specimens from sample U6 226.95 m, Mainoru Formation.

Remarks.—Our specimens differ from *C. artica*, which shows larger diameters of both large and small vesicles (79–130 μm and 8–11 μm , respectively) and a higher number of the loosely attached or closely associated small vesicles. It also differs from *C. sp.* in the Bylot Group (Hofmann and Jackson, 1994), which has a few vesicles firmly attached to a larger central one and resembles a specimen illustrated by Hermann (1990, p. 20, pl. 5.11) in the Miroedikha Formation, Siberia. It differs from *C. inaequalalis*, which is characterized by a large cell three or four times bigger than the attached smaller cells, and one cell much smaller than the others (Luo, 1991, p. 193).

Genus *Dictyosphaera* Xing and Liu, 1973

Type species.—*Dictyosphaera macroreticulata* Xing and Liu, 1973, from the Chuanlingguo Formation, Yenliao region; Chih County of Hopei, northern China, Mesoproterozoic.

Dictyosphaera macroreticulata Xing and Liu, 1973

2015 *Dictyosphaera macroreticulata*; Agic et al., p. 32, figs. 2–4.

Lectotype.—Specimen originally described as *Dictyosphaera sinica* Xing and Liu, 1973, from the Chuanlingguo Formation, Yenliao region, Chih County of Hopei, northern China, Mesoproterozoic, and junior synonym of *D. macroreticulata* Xing and Liu (1973, pl. I:18) (Agic et al., 2015).

Figure 3. Size frequency distribution of leiospheres: (1) Size frequency distribution of all *Leiosphaeridia crassa/jacutica* (dark-, medium-, and light-brown walls); (2) Size frequency distribution of dark-brown *Leiosphaeridia crassa/jacutica*; (3) Size frequency distribution of medium-brown *Leiosphaeridia crassa/jacutica*; (4) Size frequency distribution of light-brown *Leiosphaeridia crassa/jacutica*; (5) Size frequency distribution of all *Leiosphaeridia minutissima/tenuissima* (medium- and light-brown walls); (6) Size frequency distribution of light-brown *Leiosphaeridia minutissima/tenuissima*; (7) Size frequency distribution of medium-brown *Leiosphaeridia minutissima/tenuissima*.

Occurrence.—Paleoproterozoic and Mesoproterozoic of China (Ruyang and Gaoshanhe Groups) (Xing and Liu, 1973), Australia (Roper Group) (Javaux et al., 2001), Belt Supergroup (Adam, 2014).

Description.—Only three specimens observed in the Roper population, one specimen measured: 50 µm in diameter with polygonal plates less than 2 µm wide. No excystment structure observed.

Materials.—Three specimens in basal mudstones of the Velkerri Formation (sample GG1 48.75 m).

Remarks.—Agic et al. (2015) revised the taxonomy of the genus *Dictyosphaera* and synonymized all the species previously described (*D. delicata*, *D. sinica*, *D. gyrorugosa*, *D. incrassata*) to the senior species *D. macroreticulata*, described as 10 to 300 µm vesicles ornamented by a reticulate polygonal pattern consisting of interlocking 1–6 µm polygonal plates. Excystment by pylome or medial split. Because the holotype was not available for re-examination, they selected a lectotype from the same material as the holotype. In their original diagnosis, Hu and Fu (1982) described a reticulate surface ornamentation, but did not comment on its fine structure. TEM analysis by Yin et al. (2005) subsequently demonstrated that the wall is made of interlocked polygonal plates 1–3 µm wide, perforated by nanopores observed with SEM on both the exterior and interior vesicle surfaces (Kaufman and Xiao, 2003). The wall ultrastructure is multilayered (FIB-EM analyses; Schiffbauer and Xiao, 2009), and excystment by partial rupture or a circular opening (pylome) has also been observed (Yin et al., 2005).

Dictyosphaera macroreticulata is reported from the ~1580–1460 Ma Lower Belt Group, USA (Adam, 2014), as well as the 1400–1700 Ma Ruyang and broadly correlative Gaoshanhe groups of China, where it co-occurs with abundant *Shuiyousphaeridium macroreticulatum*, an acanthomorph with similar wall ornamentation but bearing many processes (Xiao et al., 1997; Schiffbauer and Xiao, 2009). In the Chinese assemblages, *Dictyosphaera* specimens may include life cycle or taphonomic variants of *Shuiyousphaeridium* (Xiao et al., 1997) that either lost or never formed the outer wall layer from which processes arise (Javaux et al., 2004). The Chinese population includes vesicles ranging from 28 to 240 µm in diameter, with 1–4 µm platelets (Agic et al., 2015). In the Roper Group, however, *D. macroreticulata* (= *D. delicata*) is rare and *Shuiyousphaeridium* absent. *Dictyosphaera* possibly occurs, as well, in the ~1000 Ma Stoer and lower Torridon groups, Scotland (Javaux, personal observation, 2008), although it is unnamed in Strother et al. (2011), who described a population as ellipsoidal fossils with walls made of highly ordered circular pits, creating a reticulate pattern and, therefore, differing from the plate-like wall structure of the Mesoproterozoic *Dictyosphaera*.

Kaufman and Xiao (2003) suggested that *D. macroreticulata* (= *D. delicata*) was a photosynthetic eukaryote based on its complex morphology and C-isotopic composition. Neither morphology nor isotopic composition, however, is diagnostic with respect to energy metabolism, although the eukaryotic nature of this ornamented acritarch is convincing.

Functionally, *D. macroreticulata* is most likely a cyst or resting stage common to the life cycles of metabolically diverse eukaryotes (see below).

Recently, Tang et al. (2015) described a new species, *D. tacita*, based on two specimens that differ from the other species by their smooth external surface and the presence of hexagonal platelets only on the interior vesicle surface. The hexagons are smaller (0.5–0.9 µm) and the vesicle diameter larger (100–120 µm) than those of *D. macroreticulata* (2–6 µm platelets, 10–20 µm vesicle diameter), *D. sinica* (0.5–1.5 µm platelets, 15–45 µm vesicle diameter), and *D. delicata* (1–3 µm platelets, 50–300 µm vesicle diameter). However, Agic et al. (2015) proposed a synonymy among *D. delicata*, *D. macroreticulata*, and other species of the genus based on the overlapping size range of the vesicles and wall platelets, and similar morphologies. Tang et al. (2015) argued that this needs reevaluation.

Genus *Eomicrocystis* Golovenok and Belova, 1986

Type species.—*Eomicrocystis magilca* Golovenok and Belova, 1986

Other species.—*Eomicrocystis elegans* Golovenok and Belova, 1986

Eomicrocystis magilca Golovenok and Belova, 1986 Figure 2.16–2.18

- 1986 *Eomicrocystis magilca* Golovenok and Belova, p. 95 [English version p. 89], pl. 7., figs. 5–7.
1989 *Eomicrocystis magilca*; Jankauskas et al., p. 91, pl. 19, fig. 7.
1994 *Eomicrocystis magilca*; Hofmann and Jackson, p. 25, pl. 18, figs. 2–4.
1997 *Eomicrocystis magilca*; Cotter, p. 258, fig. 7A, B.
2016 *Eomicrocystis magilca*; Baludikay et al., 2016, p. 179, fig. 12f.

Holotype.—*Eomicrocystis magilca* Golovenok and Belova, 1986, pl. 7, fig. 5, from the Maligna Formation in the Uchur-Maya region, eastern Siberia.

Description.—Small ovoid or spheroidal colonies of light brown, loosely packed, small spheroidal to ovoid vesicles of uniform size, sometimes dividing by binary fission, without enclosing envelope. Three colonies observed, with cells 3 µm wide and 6–7 µm long.

Occurrence.—Mesoproterozoic and early Neoproterozoic, Roper Group, Australia; Maligna Formation in the Uchur-Maya region, eastern Siberia (Golovenok and Belova, 1986); Bylot Supergroup, Canada (Hofmann and Jackson, 1994); Belt Supergroup, USA (Adam et al., 2016); Mbuyi-Mayi Supergroup, RDC (Baludikay et al., 2016).

Materials.—Three colonies in samples U5 125.1 m from the Jalboi Formation and U6 230.8 m from the Mainoru Formation.

Remarks.—*Eomicrocystis* differs from the genus *Coleogleba* (Strother et al., 1983) in lacking an organic matrix or distinct

envelope enclosing the cell clusters, and from the genus *Coniunctiophycus* by the absence of a single dense mass less than a micron in diameter within cells, the smaller cell size (10 µm in *C. sp.*), and the shape of the colony described in the Belt Supergroup as “spheroidal colony of tens of individuals, from which a wide, linear extension of more cells emerges and folds back onto itself to form a single reticulate fold” (Adam et al., 2016, p. 16). It also differs from described species of *Myxococcoides* (Schopf, 1968) in the size and organization of constituent cells. *Eomicrocystis malgica* differs from *E. elegans* by the smaller size of the cells’ minimum diameter (3–5 µm versus 6–9 µm) and more regular shape of the aggregate. The Roper colonies have cell diameters intermediate between the two species, but also have an irregular aggregate shape, and therefore are identified as *E. malgica*.

Genus *Gemmuloides* Samuelsson and Butterfield, 2001

Type species.—*Gemmuloides doncooki* Samuelsson and Butterfield 2001

cf. *Gemmuloides doncooki* Samuelsson and Butterfield, 2001
Figure 4.1

2001 *Gemmuloides doncooki* Samuelsson and Butterfield, p. 248, fig 7, D–F.

2014 *Gemmuloides doncooki*; Adam, p. 35, fig. 13.

Holotype.—*Gemmuloides doncooki* Samuelsson and Butterfield, 2001, p. 248, 249, GSC 117042 (Fig. 7D), Lone Land Formation, NW flank of Cap Mountain (63°24'11"N, 123°14'12"W), Canada, approximately 2 m above carbonate ledge. Sample 94-LL-8. GSC loc. C-404520.

Description.—Two spheromorphs, 260 and 85 µm diameter, with chagrinat wall were observed, each with a dark central sphere; only one shows evidence of budding. The presence of a dark central body is not included in the original description, but this may reflect taphonomic rather than systematic differences. The presence of a bud allies the Roper fossils with *Gemmuloides doncooki*.

Occurrence.—Roper Group, Australia; Lone Land Formation, Canada (Samuelsson and Butterfield, 2001); Belt Supergroup, USA (Adam, 2014).

Materials.—Two adjacent specimens in samples A82/3 328.35 m from the Jalboi Member and U6 240.2 m from the Mainoru Formation.

Remarks.—The Roper assemblage includes another budding spheromorph, *Blastanosphaera kokkoda*, which differs from cf. *G. doncooki* by its colonial habit, smaller diameter, thinner chagrinat wall with thin folds, and multiple buds of larger size relative to the mother cell, as well as by the presence of circular scars left by detached buds. *Coneosphaera sp.* in the Bylot Group (Hofmann and Jackson, 1994) has several smaller vesicles attached to a central one, resembling a specimen illustrated by Hermann (1990, p. 20, pl. 5.11) from the Miroedikha Formation, Siberia, which also differs from cf.

G. doncooki. *Gemmuloides doncooki* is also reported in the Belt Supergroup, Montana, USA (Adam, 2014).

Genus *Leiosphaeridia* Eisenack, 1958, emend. Downie and Sarjeant, 1963, emend. Turner, 1984

Type species.—*Leiosphaeridia baltica* Eisenack, 1958.

Remarks.—Jankauskas (1989) revised the taxonomy of the genus *Leiosphaeridia* (see for detailed synonymy) and proposed an operational approach to species recognition within the genus *Leiosphaeridia*, essentially diagnosing species based on a combination of two characters: size and wall texture. Subsequent workers have tended to follow this scheme, with some modifications (e.g., Butterfield et al., 1994; Hofmann and Jackson, 1994). Jankauskas (1989) discriminated four smooth-walled *Leiosphaeridia* species: *L. crassa* and *L. jacutica* are thick-walled leiospheres, smaller or larger than 70 µm in diameter, respectively; *L. minutissima* and *L. tenuissima* are thin-walled vesicles, again smaller or larger than 70 µm in diameter, respectively. A fifth species, *L. ternata* differs from other species in having a distinctively rigid, opaque wall that fractures radially. *Chuararia circularis* is also a smooth-walled spheromorph, but can be discriminated from the leiospheres by its much thicker wall (at least 2 µm thick), concentric folds and wrinkles, and large diameter (0.43–3.5 mm), leaving textured imprints on bedding surfaces (Butterfield et al., 1994).

The difficulty of applying the modified Jankauskas classification lies in the potential challenge of estimating wall thickness (underscored by Butterfield et al., 1994) and in classifying populations that do not fit neatly within the proposed size classes, as also noticed by Porter and Riedman (in press) in populations from the Neoproterozoic Chuar Group. Thus, while Butterfield et al. (2004) and Hofmann and Jackson (1994) reported a taxonomic break at 70 µm, there is little in the size frequency diagrams they present to justify this. Wall thickness has commonly been estimated on the basis of color or fold morphology, but wall color can vary as a function of taphonomy, thermal maturity, or original composition. Butterfield (in Butterfield et al., 1994, p. 11–12) has discussed the distinction between the thickness of folds and the thickness of the wall, which are not necessarily correlated. Previous study of wall ultrastructure in different *Leiosphaeridia* species from the Roper Group (Javaux et al., 2003, 2004) showed that *L. crassa* with thick lanceolate folds had a thinner wall than *L. tenuissima* with thin sinuous folds. We suggest that fold morphology, which reflects the taphonomy of walls with biological differences in flexibility, provides a more objective criterion than wall thickness or color. In this view, *L. crassa* and *L. jacutica* have thick lanceolate folds, whereas *L. minutissima* and *L. tenuissima* have thin sinuous folds.

Size frequency distribution presents a second complication, because many leiosphaerid populations transgress the 70 µm boundary taken to separate species. For example, we measured the minimum diameter of specimens of different color (dark brown, medium brown, light brown) and fold morphology (broad lanceolate or thin sinuous folds) within the Roper assemblage and observed no size break around 70 µm in these different morphotypes (Figs. 3.1–3.7, 4.4–4.8). This difficulty

Figure 4. Photographs of Roper organic-walled microfossils (color figures are available in the online version of this paper): (1) cf. *Gemmuloides doncooki*. (2, 3) *Leiosphaeridia atava*. (4) Light-brown *Leiosphaeridia crassaljacutica*. (5) Medium-brown *Leiosphaeridia crassaljacutica*. (6) Dark-brown *Leiosphaeridia crassaljacutica*. (7) Light-brown *Leiosphaeridia minutissima/tenuissima*. (8) Medium-brown *Leiosphaeridia minutissima/tenuissima*. (9) *Leiosphaeridia ternata*. (10–12) *Leiosphaeridia* sp., (11) showing details of wall texture of specimen in (10). Scale bar in (1) is: (1) 85 μ m; (2) 12 μ m; (3) 15 μ m; (4) 14 μ m; (5) 17 μ m; (6) 10 μ m; (7–8) 6 μ m; (9) 90 μ m; (10) 30 μ m; (11) 60 μ m; (12) 10 μ m. Slides and England coordinates are (1) U6 230.8 m .2 L2Y/1; (2) U6 305.1 m.2A Q26 ¾; (3) U6 305.1 m.2A U37/1; (4, 7) U6 230.8 m .2 H46/G46 (area); (5) U6 240.2 m .2 O34/3; (6) U6 305.1 m .2A T26/1; (8) U6 305.1 m .2A U20; (9) U5 125.1 m; (10, 11) U6 305.1 m 2A N20; (12) U6 230.8 m.2 S24/2.

has also been underlined by Porter and Riedman (2016) for Chuar Group populations. We suggest that species should be distinguished on the basis of modal rather than maximum diameter, so that *Leiosphaeridia* with lanceolate folds and a modal size <70 µm would be assigned to *L. crassa*, whereas populations with lanceolate folds and a modal size >70 µm would be placed in *L. jacutica*. This has the advantage of removing ambiguity in size frequency distributions while retaining the species distinctions used in many previous publications.

Based on the presence of a multilayered recalcitrant wall, Roper leiospheres have been interpreted as eukaryotic (Javaux et al., 2004). In the absence of supporting TEM analyses of wall ultrastructure, this attribution cannot be extended to all Proterozoic leiospheres; very likely the genus *Leiosphaeridia* is polyphyletic and their simple morphologies may record both prokaryotes and eukaryotes. Occasionally, medial split excystment structures have been observed in Roper specimens, suggesting that at least some of these fossils were resting cysts; however, even here, caution is advisable, because baeocyte-producing cyanobacterial cells can split in ways that resemble medial split excystment (Waterbury and Stanier, 1978, p. 13, fig. 4).

Leiospheres may occur as isolated specimens assigned to *Leiosphaeridia*, compact colonies called *Synsphaeridium* spp., or loose colonies named *Symplastosphaeridium* spp., possibly reflecting cyst and vegetative stages of the same population or life stages of different organisms. Single leiospheres might also be detached specimens from a colony (Hofmann and Jackson, 1994). The simple morphologies of leiospheres make it difficult to choose among these hypotheses, but more detailed analyses of wall ultrastructure and chemistry may provide the requisite tests (Javaux et al., 2004; Javaux and Marshall, 2006).

Leiosphaeridia atava (Naumova, 1960) Jankauskas,
Mikhailova, and Hermann, 1989
Figure 4.2–4.3

- 1960 *Megasacculina atava* Naumova, pl. 3, fig. 15.
1989 *Leiosphaeridia atava* (Naumova, 1960); Jankauskas et al., p. 74, pl. 10, figs. 4–7.
2016 *Leiosphaeridia atava*; Sergeev et al., fig. 4.5.

Holotype.—Preparation 452/1, paleontological collection at the Institute of Precambrian Geology and Geochronology, St. Petersburg, Russia, upper Riphean (Tonian), Lakhanda Group, Neryuen Formation, Uchur-Maya region, Siberia. (The holotype was lost, as mentioned by Sergeev and Lee, 2006).

Occurrence.—The Mainoru Formation, Roper Group, Australia; the Lakhanda Group, Neryuen Formation, Uchur-Maya region, Siberia (Jankauskas, 1989); the Koltasy Formation, Russia (Sergeev et al., 2016); the El Mreiti Group, Taoudeni Basin, Mauritania (Beghin et al., in review).

Description.—Spheroidal to oval vesicle with a fine granular, flexible wall, with numerous folds, 46 to 56 µm in diameter (N = 4); two specimens with a dark, internal bleb of organic matter. No excystment structures observed.

Materials.—Four specimens observed in sample U6 230.8 m from the Mainoru Formation.

Remarks.—*Leiosphaeridia atava* differs from *L. obsuleta* by its diameter larger than 70 µm (Jankauskas, 1989).

Leiosphaeridia crassa (Naumova, 1949), emend. Jankauskas
in Jankauskas, Mikhailova, and Hermann, 1989
Figure 4.4–4.6

- 1949 *Leiotriletes crassus* Naumova, p. 54, pl. 1, figs. 5, 6; pl. 2, figs 5, 6.
1989 *Leiosphaeridia crassa*; Jankauskas in Jankauskas et al., p. 75, pl. 9, figs. 5–10.
1989 *Leiosphaeridia minutissima*; Jankauskas et al., p. 75, pl. 9, figs. 2, 3.

Holotype.—No holotype was designated by Naumova (1949), from the Lontova Formation, lower Cambrian, Estonia. A lectotype was designated by Jankauskas (in Jankauskas et al., 1989, p. 75) from Naumova (1949, pl. 1, fig. 3), but this specimen was part of *Leiotriletes simplicissimus*, which is a species that Jankauskas et al. (1989) synonymized with a different species of *L. minutissima* (Porter and Riedman, 2016).

Emended diagnosis.—A species of *Leiosphaeridia* with smooth, pliant walls with lanceolate folds and a modal diameter of less than 70 µm.

Occurrence.—Proterozoic and lower Paleozoic, worldwide.

Description.—Smooth-walled leiospheres with large lanceolate folds (Fig. 3.1–3.4). Minimum diameter ranges from 5 to 390 µm (mean: 58.1 ± 40.2 µm, N = 669). No statistical differences among dark brown, medium, and light brown subpopulations, with mean diameters and standard deviations of, 54.5 ± 21.6 µm (N = 61), 55.3 ± 30.7 µm (N = 191 µm), and 56.0 ± 27.7 µm (N = 116). Excystment by partial rupture and medial split.

Materials.—These are the most common microfossils in the Roper assemblage, especially in samples U6 305.1 m from the Mainoru Formation and U5 125.1 m from the Jalboi Member.

Remarks.—As noted above, the rationale for emending the diagnosis of this species stems from the desire to focus on observed rather than inferred wall characters and to articulate size distinctions in a way that will minimize ambiguity in observed populations. The emended diagnosis considers the presence of lanceolate folds on a smooth wall as a diagnostic character as opposed to the wall color, which is not considered as a valid character.

Leiosphaeridia jacutica (Timofeev, 1966), emend. Mikhailova
and Jankauskas in Jankauskas, Mikhailova, and Hermann, 1989
Figure 4.4–4.6

- 1966 *Kildinella jacutica* Timofeev, p. 30, pl. 7, fig. 2.

1989 *Leiosphaeridia jacutica* (Timofeev, 1966); Mikhailova and Jankauskas in Jankauskas et al., 1989, p. 77, pl. 9, fig. 12; pl. 12, figs. 3, 6, 7, 9.

Holotype.—Preparation number 452/1, Biostratigraphy Laboratory, Maya River Collection, late Mesoproterozoic/early Neoproterozoic Lakhanda Group, Russia (Timofeev, 1966, pl. 7, fig. 2).

Emended diagnosis.—A species of *Leiosphaeridia* characterized by smooth, pliant walls with lanceolate folds and a modal diameter greater than 70 μm .

Occurrence.—Proterozoic worldwide.

Description.—A species of *Leiosphaeridia* characterized by smooth, pliant walls with lanceolate folds and a modal diameter greater than 70 μm . Excystment by partial rupture and medial split. While we cannot exclude the possibility that these represent a long right-hand tail of the *L. crassa* population, we suspect that, by comparison to other mid-Proterozoic assemblages, distinct populations of large leiosphaerids were present in the Roper seaway.

Materials.—The Roper assemblage contains a relatively small proportion of very large, smooth walled leiosphaerids, in samples U6 305.1 m and 240.2 m from the Mainoru Formation and sample GG1 326.2 m from the Corcoran Formation.

Remarks.—As noted above, the rationale for emending the diagnosis of this species stems from the desire to focus on observed rather than inferred wall characters and to articulate size distinctions in a way that will minimize ambiguity in observed populations. The emended diagnosis considers the presence of lanceolate folds on a smooth wall as a diagnostic character, as opposed to wall color, which is not considered as a valid character.

Leiosphaeridia minutissima (Naumova, 1949), emend.

Jankauskas in Jankauskas, Mikhailova, and Hermann, 1989

Figure 4.7–4.8

1949 *Leiotreletes minutissimus* Naumova, p. 52, pl. 1, figs. 1, 2; pl. 2, figs. 1, 2.

1989 *Leiosphaeridia minutissima* (Naumova); Jankauskas in Jankauskas et al., p. 79, pl. 9, figs. 1, 4, 11.

Lectotype.—No holotype was designated by Naumova (1949). Jankauskas (in Jankauskas et al., 1989, p. 80) designated a specimen of *Leiotreletes minutissimus* (pl. 1, fig. 1) from Naumova (1949) as lectotype.

Emended diagnosis.—A species of *Leiosphaeridia* characterized by smooth walls with sinuous folds and a modal diameter less than 70 μm .

Description.—Smooth-wall spheromorphs with sinuous folds and a modal diameter less than 70 μm . Minimum diameter

21–117 μm (mean: $50.6 \pm 18.2 \mu\text{m}$, $N = 216$) (Figure 3.5–3.7). Light brown specimens 21–117 μm in minimum diameter ($N = 116$, mean: $50.8 \pm 17.9 \mu\text{m}$) and medium brown specimens 27–111 μm ($N = 47$, mean: $49.6 \pm 19.1 \mu\text{m}$). No dark brown specimens observed.

Occurrence.—Proterozoic worldwide.

Materials.—Common in inshore facies of the Roper Group, especially in samples U6 305.1 m, and U6 273.7 m from the Mainoru Formation.

Remarks.—As noted above, the rationale for emending the diagnosis of this species stems from the desire to focus on observed rather than inferred wall characters and to articulate size distinctions in a way that will minimize ambiguity in observed populations. The emended diagnosis considers the presence of sinuous folds on a smooth, thin wall as a diagnostic character, as opposed to wall color, which is not considered as a valid character.

Leiosphaeridia tenuissima Eisenack, 1958 emend.

Figure 4.7–4.8

1958 *Leiosphaeridia tenuissima* Eisenack, p. 391, pl. 1, figs. 2, 3.

1989 *Leiosphaeridia tenuissima*; Jankauskas et al., p. 81, pl. 9, fig. 13.

Holotype.—Preparation A3, 3 number 4 from the *Dictyonema*-shales of the lower Ordovician, St Petersburg area, Russia (Eisenack, 1958, pl. 1, fig. 2).

Emended diagnosis.—A species of *Leiosphaeridia* characterized by smooth walls with sinuous folds and a modal diameter (rather than maximum diameter) greater than 70 μm ; the wall color is not a diagnostic criteria.

Description.—Smooth wall spheromorphs with sinuous folds and a modal diameter greater than 70 μm . These may reflect a larger, uncommon population of *Leiosphaeridia* in Roper shales.

Occurrence.—Proterozoic worldwide.

Materials.—Uncommon specimens in samples U6 305.1 m and U6 230.8 m from the Mainoru Formation.

Remarks.—As noted above, the rationale for emending the diagnosis of this species stems from the desire to focus on observed rather than inferred wall characters and to articulate size distinctions in a way that will minimize ambiguity in observed populations. The emended diagnosis considers the presence of sinuous folds on a smooth, thin wall as a diagnostic character as opposed to wall color, which is not considered as a valid character.

Leiosphaeridia ternata (Timofeev, 1966), emend. Mikhailova and Jankauskas in Jankauskas et al., 1989
Figure 4.11

- 1966 *Turuchanica ternata* Timofeev, p. 45, pl. 9, fig. 8.
1989 *Leiosphaeridia ternata* (Timofeev); Mikhailova and Jankauskas in Jankauskas et al., p. 81, pl. 11, figs. 2–4; pl. 12, figs. 4, 5, 8.
2016 *Leiosphaeridia ternata*; Sergeev et al., fig. 4.3, 4.4.

Holotype.—Preparation 169/1, Biostratigraphical laboratory LAGED AN SSSR, Turukhansk collection, lower Tungunsk, Turukhansk district; Miroedikhinsk series, Riphean (Mesoproterozoic and early Neoproterozoic boundary), rarely Ordovician (Timofeev, 1966).

Occurrence.—Found globally in worldwide Proterozoic successions.

Description.—Compressed opaque spheromorph with thick, rigid walls commonly showing characteristic radial fractures. Diameter 15 to 110 μm .

Materials.—A few specimens were observed in samples A82/3 157.5 m in the Jalboi Member, GG1 326.2 m in the Corcoran Formation, and U6 305.1 m in the Mainoru Formation.

Leiosphaeridia sp.
Figure 4.10–4.12

Description.—Large medium to dark brown spheroidal to oval vesicles with a characteristic cork-like wall texture made of 5–11 μm , irregular patchy areas of different colors and fabric; this texture may well be taphonomic, but if so, it reflects original differences in wall composition, compared to other leiosphaerids. Concentric folds at the periphery. The minimum diameter of 19 spheroidal specimens is 56–455 μm (mean: $159.8 \pm 96.3 \mu\text{m}$). Three oval specimens measured 75–210 μm wide and 160–330 μm long.

Materials.—22 specimens in the Gibb Member, samples U6 305.1 m, U6 230.8 m of the Mainoru Formation, and in sample GG1 171.5 m of the Corcoran Formation.

Remarks.—This species differs from another large leiosphere *L. jacutica* by its particular cork-like wall texture and a morphology that ranges from spheroidal to ovoidal. It also differs from *Chuarina circularis*, which has a thicker opaque, smooth wall. These specimens are left in open nomenclature until further characterization by SEM and TEM.

Genus *Lineamorph*a Vorob'eva, Sergeev, and Yu, 2015

Type species.—*Lineamorph*a *elongata* Vorob'eva, Sergeev, and Yu, 2015, by monotypy.

*Lineamorph*a *elongata* Vorob'eva et al., 2015
Figure 5.1–5.4

- 2004 “large striated tubes” Javaux et al., p. 126, fig 3 g–k.
2015 *Lineamorph*a *elongata*; Vorob'eva et al., p. 216, figs. 7 1–7.5.
2016 *Lineamorph*a *elongata*; Adam et al., fig. 9 A–D.

Holotype.—Figure 7.4, Vorob'eva et al., 2015, GINPC 14711-804, locality AK-14, Kotuikan River valley, Kotuikan Formation, Anabar Uplift, northern Siberia.

Occurrence.—Early Mesoproterozoic, Jalboi, Crawford, and upper Mainoru formations, Roper Group, Australia; Belt Supergroup, Montana, US (Adam, 2014); and Kotuikan Formation, northern Siberia (Vorob'eva et al., 2015).

Description.—Longitudinally striated hollow tubes (not a sheath around bundled filamentous sheaths) that often break into fragments, so maximum length is unknown but millimetric, 34 to 150 μm in diameter, fragment length: 131 to 473 μm (N = 25).

Materials.—562 specimens observed in maceration, in lower-shoreface to inner shelf facies of the Jalboi, Crawford, and upper Mainoru formations, Roper Group; one observed in thin section, 25 measured specimens. Abundant specimens observed in samples U5 125.1 m and U5 151.3 m of the Jalboi Member; in samples U5 334.3 m and U5 412.1 m of the Arnold sandstone Member; in samples A82/3 311 m of the Crawford Formation; and in samples U6 305.1 m, U6 230.8 m, and U6 240.2 m from the basal Mainoru Formation, but rare elsewhere.

Remarks.—In the Roper population, there seems to be no relation between diameter and fragment length, nor dominant fragment length, suggesting random fragmentation of longer, probably millimetric, tubes. Light microscopy shows longitudinal, micron-scale striations along the tubes while SEM reveals a thick multilayered wall of densely packed granules, but no longitudinal striations. At the ultrastructural level (TEM), however, transverse sections of the wall show a clear alternation of electron-dense and electron-tenuous bands that correspond in size and distribution to the striations observed by light microscopy (Javaux et al., 2004). The wall is ~1 μm thick, occasionally with an outer, electron-dense layer. The striations, thus, are not wall sculpture, but reflect original compositional heterogeneities in the tube wall, indicating complex physiological controls on wall formation.

The Roper material appears to be indistinguishable from the type of *Lineaforma elongata* from the lower Mesoproterozoic Kotuikan Formation, northern Siberia (Vorob'eva et al., 2015). In the Roper Group, these filaments occur as transported fragments, contributing less than 3% to the entire assemblage, but up to 40% in lower-shoreface to inner-shelf shales. The rounded, closed tube ends observed in the Russian population were not observed in fragmental Roper specimens. The large size and complex wall ultrastructure of these microfossils suggest a eukaryotic affinity (Javaux et al., 2004).

Figure 5. Photographs of Roper organic-walled microfossils: (1–4) *Lineaforma lineata*: (2) showing hollow extremity of specimen in (1), (3) specimen in situ in thin section. (5) *Paleolyngbya catenata*. (6–9) *Satka favosa*: (6) showing medial split and hollow interior, (8) showing hollow interior. (10) *Siphonophycus kestron* (bottom specimen) and *S. typicum* (top specimen). (11) *Siphonophycus robustum*. (12) *Siphonophycus septatum*. (13) *Siphonophycus thulenema*. (14) *Squamosphaera colonialica*. (15) *Symplassphaeridium* sp., (16–18) *Synsphaeridium* spp. Scale bar in (1) is: (1) 60 μm ; (2) 100 μm ; (3) 50 μm ; (4) 110 μm ; (5, 7) 15 μm ; (6, 8) 20 μm ; (9) 40 μm ; (10, 13) 20 μm ; (11, 12) 10 μm ; (14) 50 μm ; (15, 16) 33 μm ; (17, 18) 15 μm . Genus *Palaeolyngbya* Schopf, 1968

Type species.—*Palaeolyngbya barghoorniana* Schopf, 1968

Palaeolyngbya catenata Hermann, 1974
Figure 5.5

- 1974 *Palaeolyngbya catenata* Hermann, p. 8, pl. 6, fig. 5.
1980 *Oscillariopsis robusta*; Horodyski and Donaldson, p. 149, fig. 13H.
1994 *Palaeolyngbya catenata*; Butterfield et al., 1994, p. 61, fig. 25F–G.

Holotype.—No holotype designated by Hermann, 1974, p. 8, 9, pl. 6, fig. 5, Tonian, Miroedikha Formation, Russia.

Description.—Cellular trichome within a single encompassing sheath, cells 26 μm wide and 6 μm long.

Materials.—One fragmented specimen with ripped sheath in sample U5 130.5 m from the Jalboi Member.

Genus *Satka* Jankauskas, 1979a

Type species.—*Satka favosa* Jankauskas, 1979a

Satka favosa Jankauskas, 1979a
Figure 5.6–5.9

- 1979a *Satka favosa* Jankauskas, pl. 4, fig. 2.
1980 “polygonally segmented sphaeromorphs” Horodyski, p. 658, pl. 2, figs. 8–12.
1989 *Satka favosa*; Jankauskas et al., p. 51, pl. 4, figs. 1, 2?
1989 *Satka elongata*; Jankauskas et al., p. 51, pl. 4, figs. 3, 5.
1989 *Satka granulosa*; Jankauskas et al., p. 51, pl. 4, fig. 8.
1994 *Satka* spp. Hofmann and Jackson, pl. 18, figs. 26–31.
2001 *Satka favosa*; Javaux et al., pl. 1e, f.
2003 *Satka favosa*; Javaux et al., figs. 1–10, 11.
2004 *Satka favosa*; Javaux et al., 2004, p. 125, fig. 3a–f.

Holotype.—Specimen pl. 4, fig. 2, preparation 16-1815-635, lower and middle Riphean (Mesoproterozoic) successions of the southern Urals, Russia (Jankauskas, 1989).

Description.—Hollow oval spheromorph, 24 to 100 μm wide and 29 to 100 μm long ($N = 122$), with walls made of tessellated 6 to 16 μm (minimum diameter) polygonal plates and with no external envelope. Excystment by medial split (Fig. 5.6).

Occurrence.—*Satka favosa*, as described here, seems to be restricted to Mesoproterozoic rocks, including lower Mesoproterozoic shales of the Belt Supergroup (“polygonally segmented sphaeromorphs” of Horodyski, 1980; Adam, 2014), the Bylot Supergroup of the Canadian Arctic (Hofmann and Jackson, 1994, as *Satka* spp., pl. 18, figs. 26–31), and lower and middle Riphean (Mesoproterozoic) successions of the southern Urals (Jankauskas et al., 1989).

Materials.—Many specimens observed in shoreface facies of the Gibb Member, basal Mainoru Formation (samples U6 240.2 m, U6 273.7 m, U6 305.1 m), but rare elsewhere.

Remarks.—The wall construction of *S. favosa* identifies it as a eukaryote, most likely the resting stage of some protist. Great confusion exists in the literature concerning *Satka* and its species. Jankauskas (1989) differentiated *S. favosa* from *S. elongata* (40–70 μm) by its smaller size and the characteristic shape of its inward-curving plates; *S. colonialica* (up to 150 μm) was segregated because of its simpler regular shape and better-defined plates; and *S. granulosa* (40–50 μm wide to 75–125 μm long) was differentiated by its smaller size and granular appearance (linked to the presence of internal bodies). The specimens illustrated by Jankauskas (1989) as *Satka elongata* (pl. 4, figs. 3, 5) and *Satka granulosa* (pl. 4, fig. 8) also resemble *Satka favosa* as described here. *Satka squamifera* is described as having rounded plates and an external envelope. From our observations, however, the “plates” of *S. squamifera* represent the imprints of spheroidal cells on an encompassing envelope; therefore, we interpret this population as a colonial microorganism, perhaps cyanobacterial, which is unlikely to be linked to *S. favosa* at the domain level, and recently placed within the new genus *Squamosphaera* (Tang et al., 2015).

Genus *Siphonophycus* Schopf, 1968, emend. Knoll,
Swett, and Mark, 1991

Type species.—*Siphonophycus kestron* Schopf (1968).

Occurrence.—Widespread in Proterozoic assemblages, common throughout the Roper Group.

Description.—Fragments of smooth, non-septate tubes, commonly interpreted as the sheaths of oscillatoriacean cyanobacteria.

Remarks.—Different species are distinguished on the basis of cross-sectional diameter (revision in Butterfield et al., 1994): *S. thulenema*: 0.5 μm ; *S. septatum*: 1–2 μm ; *S. robustum*: 2–4 μm ; *S. typicum*: 4–8 μm ; *S. kestron*: 8–16 μm ; and *S. solidum*: 16–32 μm . Five species occur in Roper shales: *S. kestron*, *S. robustum*, *S. septatum* and *S. typicum* occur as transported fragments; and *S. thulenema* forms small balls of thin filamentous sheaths. *Siphonophycus* spp. are commonly interpreted as the sheaths of oscillatoriacean cyanobacteria.

- in press *Squamosphaera colonialica*; Porter and Riedman, fig. 17, 1–7. [See for complete synonymy]

Holotype.—Number 16-62-4762/22, slide 1. Well Kabakovo-62, 4762-4765 m. Neoproterozoic Zigazino-Komarovo Formation, Ufa, Bashkirian Urals (Jankauskas, 1979, fig. 4).

Description.—Single-walled, spheroidal, tomaculate, or irregularly shaped vesicles with irregular outline characterized by numerous broadly domical bulges. Vesicles 29–166 µm wide and 66–184 µm long (N = 37); individual bulges 11 to 14 µm in diameter.

Materials.—Many specimens were observed in all facies except the most basinal and are particularly abundant in the lower-shoreface to storm-dominated shelf facies of the Jalboi Member and Crawford Formation (samples A82/3 311 m, A82/3 166 m, U5 125.1 m, U5 151.3 m, U5 334.3 m, U5 412.1 m).

Remarks.—The Roper population closely matches the emended diagnosis provided by Porter and Riedman (in press). Populations assigned here to the genus *Squamosphaera* were originally classified as a species of the genus *Satka* (Jankauskas, 1979b). As discussed above, the type species of *Satka*, *S. favosa*, is characterized by a wall of tessellated plates, which is far different from the vesicles observed in *S. colonialica*. The two species should not be placed in the same genus and doubtfully belong to the same domain. Tang et al. (2015) gave formal recognition to this by segregating populations of *Satka colonialica* into the new genus. Tang et al.'s (2015) diagnosis and description suggest that *Squamosphaera* was a cyst wall ornamented by broadly domical processes, but this conflicts with the irregular morphology of individual vesicles, both within Tang et al.'s (2015) illustrated materials and populations observed elsewhere. For this reason, Porter and Riedman (in press) emended the diagnosis of *Squamosphaera*, identifying the domical surface features simply as bulges. Roper populations closely resemble those from the Chuar Group, and we interpret them as enveloped marked by imprints of internal cells no longer present.

Hofmann and Jackson (1994, p. 28) described *Satka colonialica* from the Bylot Supergroup, the Canadian Arctic, as a colony of packaged cells in “distinct belt-like rows transverse to the long axis of the colony,” with a smooth surface and distinct curvilinear folds. They further suggested that *S. squamifera*, *S. granulosa*, and *S. elongata* might be taphonomic variants of the same taxon, and mentioned *S. elongata* Jankauskas, 1989 as the senior synonym to which other species should be referred. *Satka favosa*, however, is actually the senior species of the genus *Satka* (Jankauskas, 1979b). Hofmann and Jackson (1994) also include in their suggestion of synonymy a Bylot population referred to *Satka* spp. that we interpret as *S. favosa* (see above). Several types of coccoidal cyanobacteria (Chroococcales and Pleurocapsales) and green algae (such as *Pandorina*) can produce colonies of packed spheroidal cells embedded in an envelope of amorphous mucilage matrix. Less commonly, the individual cells have a single wall rather than a multilamellate envelope, are closely packed, and the colony is surrounded in a structurally defined envelope, such as in modern cyanobacteria that produce baeocytes (endospores) within a parental wall (*Chroococcidiopsis* and *Staniera/Dermocarpa*).

Squamosphaera colonialica resembles these pleurocapsalean cyanobacteria, with the internal cells not preserved, only their imprints on the wall. *Squamosphaera* differs from *Synsphaeridium* spp., which are colonies without an envelope.

Genus *Symplassosphaeridium* Timofeev, 1959
Symplassosphaeridium sp.
Figure 5.15

Description.—Aggregates of loosely packed, smooth-walled vesicles of variable size, but with similar morphology and size within a colony. Differs from *Synsphaeridium* by the loose packing of vesicles.

Materials.—Dozens of colonies observed.

Genus *Synsphaeridium* Eisenack, 1965

Type species.—*Synsphaeridium gotlandicum* Eisenack, 1965.

Synsphaeridium sp.
Figure 5.16–5.18

Occurrence.—Widespread in Proterozoic and Phanerozoic rocks.

Description.—Aggregates of contiguous smooth-walled vesicles, sometimes with internal inclusions, without envelope. Vesicles are similar in morphology and size within a colony. Colonies have variable size, from broadly spherical to elongated and irregular. Cell diameter ranges from 4 to 40 µm, and colonies can be up to 180 µm or more in diameter.

Materials.—Dozens of colonies observed, especially in samples GG1 326.2 m, in the Corcoran Formation and in samples U5 125.1 m and U5 151.3 m of the Jalboi Member.

Genus *Tappania* Yin, 1997

Type species.—*Tappania plana* Yin, 1997.

Other species.—*Tappania tubata* Yin, 1997; *Tappania gangaei* Prasad and Asher, 2001.

Tappania plana Yin, 1997

2001 *Tappania tubata*; Prasad and Asher, p. 74, pl. 2, figs. 4–7.
2001 *Tappania gangaei*; Prasad and Asher, p. 74, pl. 2, figs. 8, 10.
2001 *Tappania plana*; Javaux et al., pl. 1a–c.
2004 *Tappania plana*; Javaux et al., p. 124, fig. 2a–e.
2009 *Tappania plana*; Nagovitsin, fig. 2 a–e.

Holotype.—Sample and slide M 9208-1, L4/37, Shuiyou section, southern Shanxi, North China; lower shales of Beidajian Formation of the Ruyang Group (Meso-Neoproterozoic) (Yin, 1997, pl. 1, fig. 7).

Description.—Size 15 to 158 μm ($N = 48$), irregularly spheroidal vesicle bearing zero to 21 tubular, heteromorphic, sometimes branching, sometimes septate processes with closed relatively dark, rounded ends; zero to four neck-like expansions; zero to three bulbous protrusions. Process length up to 8 μm ; bulbous expansions 2 μm wide; neck up to 2 μm high and 2 μm wide; two specimens show septate processes (Fig. 6.2–6.4), two others with branching processes. One specimen with a neck-like expansion shows a concentration of small (~8 μm long) processes with dark ends in one area of the vesicle surface, and another has small (3–5 μm long), hair-like spines, which are probably developing processes (not shown). The vesicle occasionally includes a dark cytoplasmic remnant. Specimens may bear only broad neck-like extensions (Fig. 6.6, 6.7, 6.10), or only processes (zero to 21) (Fig. 6.2, 6.5, 6.9, 6.13), or both. Neck-like extensions usually have a dark rim. In one specimen without processes, this trapezoidal extension is open, possibly indicating excystment (Fig. 6.15). Some specimens also show bulbous expansions suggestive of division by budding (Fig. 6.1); buds have semi-circular to oval convex morphology, whereas neck-like expansions have a trapezoidal shape, with side walls flaring outward and a convex end.

Occurrence.—*Tappania plana* seems to be restricted to uppermost Paleoproterozoic and Mesoproterozoic rocks, including, in addition to the Roper Group, Australia (Javaux et al., 2001); the Ruyang Group, China (Xiao et al., 1997; Yin, 1997); the Bahraich and Kheinjua groups, India (Prasad and Asher, 2001; Prasad et al., 2005); the Kamo Group of Siberia (Nagovitsin 2009; Nagovitsin et al., 2010); and the Lower Belt Group, USA (Adam, 2014).

Materials.—48 specimens measured in samples, U5 151.3 m and U5 130.5 m from the Jalboi Formation (proximal shelf facies), and from GG1 340.2 m and GG1 326.2 m from the Corcoran Formation (TST, distal shelf facies).

Remarks.—We observed a wide range of morphologies within *Tappania*, ranging from specimens with only broad, neck-like extensions, or only processes, to individuals with both broad, neck-like extensions and processes. On one fragmented specimen bearing a neck-like expansion, very small processes with dark, rounded closed ends are locally grouped on the vesicle wall. This is the first time this morphology has been reported in *Tappania plana*, however a single fragmented specimen and the large variability of the species precludes the creation of a new

species at this time. Rare specimens show processes with septa, suggesting *Tappania* was multicellular. Ultrastructural analyses show a unilayered homogenous wall (Javaux et al., 2004). The Roper population shows division by budding, and possible excystment through the opening of a neck-like extension. Specimens from the Kotuikan Formation illustrated by Nagovitsin (2009) suggest that *Tappania* could also reproduce by a simple binary division of the vesicle.

Yin (1997) described a second species of *Tappania*, *T. tubata*, that co-occurs with *T. plana* and has a broad tube-like extension but not trapezoidal neck-like extension, with a fimbriate distal margin and a few small processes on its extension surface. The Roper *Tappania* population displays the range of morphological characters originally ascribed to *T. plana* and *T. tubata*, occasionally on a single specimen. Therefore, we consider *T. tubata* to be a synonym of the senior species, *Tappania plana*. Prasad and Asher (2001) described a third species, *Tappania gangaei*, based on the rounded bulbous extension, rather than trapezoidal or tube-like. However, in the Roper population, specimens may bear both neck-like and rounded extension (interpreted as budding structures), therefore here too, we consider *T. plana* as the senior synonym.

Vesicles bearing neck-like expansions but no processes are reported as cf. *Tappania?* in the late Mesoproterozoic–early Neoproterozoic Mbuyi-Mayi Supergroup, RDC (Baludikay et al., 2016). However, the absence of processes on any of the six specimens observed so far and the younger age of these fossils leaves this occurrence ambiguous, even though *Tappania* populations elsewhere also include similar morphologies without processes. Indeed, so far, *Tappania plana* seems to be restricted to uppermost Paleoproterozoic to Mesoproterozoic rocks. Butterfield (2005a) described specimens from the mid-Neoproterozoic Wynniatt Formation, the Canadian arctic as *Tappania*, but these show a complex pattern of septation, peripheral branching and anastomosis not found in Mesoproterozoic populations and lack the neck-like expansions or the closed and rounded process terminations characteristic of older fossils. Therefore, the Neoproterozoic population might usefully be placed into a separate genus.

Genus *Tortunema* Hermann, 1976

Type species.—*Tortunema wernadskii* (Schepeleva, 1960) Butterfield et al., 1994.

Tortunema sp. Figure 6.16

Description.—Fragmental remains of compressed cylindrical sheaths, 250–300 μm long and 30 μm wide ($N = 2$), marked by thin, regularly spaced, transverse annulations that record cell boundaries of originally ensheathed trichomes. Spacing of

Figure 6. (16) *Tortunema* sp. (17, 18) *Trachytrichoides* sp.: (18) showing details of cells morphology in filaments in (17). Scale bar in (1) is: (1, 2) 40 μm ; (3, 11) 10 μm ; (4, 8, 14) 20 μm ; (5, 9, 16, 17) 30 μm ; (6, 10, 12, 15, 18) 15 μm ; (7) 27 μm ; (13) 25 μm . Slide and England finder coordinates: (1) GG1 340.2 m .3 B X36/2, (2, 3) GG1 340.2 m .2 A J47/2, (4) GG1 340.2 m .3B T40/2, (5) GG1 340.2 m .2A E28/4, (6) U5 151.3 m .2 Q28/3, (7) GG1 326.2 m .2 V33/1, (8) U5 151.3 m .2 Y14/2, (9) GG1 340.2 m .3 H26/2, (10) GG1 326.2 m .3 F39/1, (11, 12) GG1 340.2 m .2 E17/1, (13) GG1 326.2 m .2 Y28/4, (14) GG1 340.2 m .3 O19/1, (15) U5 130.5 m .2 U9, (16) A82/3 379.1M G57/0, and (17) U6 240.2 m .2B J34/1.

prominent annulations 6 μm , commonly with less-pronounced annulations between them.

Materials.—Two specimens.

Discussion.—Pseudoseptate filaments, widely distributed in Proterozoic platform and inner-shelf shales, are generally interpreted as the empty sheaths of cyanobacteria (e.g., Jankauskas, 1989; Butterfield et al., 1994). These sheaths are larger than the type species of the genus, *T. wernadskii* (Schepeleva) Butterfield. Because they are rare, we have little sense of their size frequency distribution, so only identify them as *Tortunema* sp.

Genus *Trachytrichoides* Hermann in Timofeev, Hermann, and Mikhailova, 1976

Type species.—*Trachytrichoides ovalis* Hermann in Timofeev et al., 1976.

Trachytrichoides sp.
Figure 6.17–6.18

Description.—Multicellular filaments with ovoid cells and thick intercellular septa, no external sheath, 157 μm long and 5 μm wide (N = 3), with individual ellipsoidal cells 5 μm wide x 6 μm long.

Materials.—Three filaments observed in sample U6 240.2 m of the Mainoru Formation.

Remarks.—A rare component of the Roper Group, differs from other filamentous taxa by the oval shape of the cells and absence of ellipsoidal fold between the cells (as in *Arctacellularia*), and from the type species *T. ovalis* by the smaller cell size than those of the holotype (25–35 μm wide and 30–60 μm long).

Genus *Valeria* Jankauskas, 1982, emend. Nagovitsin, 2009

Type species.—*Valeria lophostriata* (Jankauskas, 1979b) Jankauskas, 1982.

Valeria lophostriata (Jankauskas, 1979b) Jankauskas, 1982

(For additional synonymy see Jankauskas et al., 1989, and Hofmann and Jackson, 1994)

Holotype.—Number 16-62-4762/16, sp. 1, DH Kabakovo 62 drill core, depth 4762 to 4765 meters, Neoproterozoic Zigazino-Komarovo Formation, southern Urals (Jankauskas, 1979b, fig. 1.14).

Description.—Large vesicle, 104–160 μm in minimum diameter, with lanceolate folds and a distinctive ornamentation of concentric ridges, giving the appearance of a “target” (Fig. 7.3, 7.4).

Occurrence.—This taxon is found worldwide (Hofmann, 1999) from the late Paleoproterozoic Era (Javaux et al., 2004; Lamb et al., 2009; Peng et al., 2009) to the Cryogenian (Nagy et al., 2009).

Materials.—Several specimens observed, mostly in samples U6 305.1 m, U6 273.7 m, and U6 240.2 m from the Mainoru Formation.

Remarks.—SEM analyses show that the striations are 1- μm ridges located on the inside of the vesicle wall (Javaux et al., 2004). Excystment by medial split gives rise to two half vesicles that commonly enroll onto themselves (Fig. 7.1, 7.2).

Unnamed form A
Figure 7.5–7.6

Description.—A large ovoidal or irregular and globular envelope including several contiguous compartments, each surrounded by an envelope and containing closely packed spheroidal cells. Two fragmented specimens are 350 μm wide and 600–700 μm long, internal compartments surrounded by an inner envelope 39–85 μm in diameter, containing poorly defined, closely packed cells. The external envelope is 8–13 μm thick.

Materials.—Two specimens in sample U6 305.1 m from the Mainoru Formation.

Unnamed form B
Figure 7.7–7.8

Figure 7. Photographs of Roper organic-walled microfossils: (1–4) *Valeria lophostriata*: (1) showing half enrolled vesicle following medial split, (2) showing start of medial split, (3, 4) showing wall ornamentation by characteristic concentric striations. (5, 6) Unnamed form A, large compartmentalized colonial forms. (7, 8) Unnamed form B, opaque spheromorph, (8) showing details of folds at periphery. (9) Unnamed form C, spheromorphs connected by a filamentous expansion. (10) Unnamed form D, spheromorph with a filamentous expansion. (11) Unnamed form E, large smooth thick brittle spheromorph. (12) Unnamed form F, large filament in indented sheath. Scale bar in (1) is: (1) 100 μm , (2, 4, 8) 25 μm , (3) 10 μm , (5) 70 μm , (6) 120 μm , (7) 45 μm , (9) 18 μm , (10, 15) 30 μm , (11) 80 μm , and (12) 55 μm . Slide and England finder coordinates: (1) U6 305.1 m .2A S41, (2) U6 230.8 m .2 N27/2, (4) U6 233.6 B45/0, (5) U6 305.1 m .2A O/N39, (6) U6 305.1 m B45/1, (7) GG1 340.2 m .3B U30, (9) U5 125.1 m .2 M41/3, (10) GG1 326.2 m .2 E20/1, (11) U6 240.2 m .2U27/2, (12) U5 436.7 m .2 S51.

Description.—Black opaque vesicles, 141 and 215 μm in diameter (N = 2), with medial split and folds at periphery.

Materials.—Two specimens in sample GG1 340.2 m from the Corcoran Formation.

Remarks.—These vesicles differ from *Chuarina circularis* by the translucent margin showing folds.

Unnamed form C
Figure 7.9

Description.—Vesicles with smooth to chagrinat walls, 30 and 35 μm in diameter (N = 2), connected by a 14- μm -long filamentous expansion.

Materials.—Two vesicles in sample U5 125.1 m from the Jalboi Member.

Unnamed form D
Figure 7.10

Description.—Vesicle 40 μm in diameter, attached to a large 80 μm filamentous expansion, but not communicating with the cell interior (thus distinct from *Germinosphaera*).

Materials.—One specimen in sample GG1 326.2 m from the Corcoran Formation.

Unnamed form E
Figure 7.11

Description.—Large, smooth-walled, thick, brittle, brown-orange wall fragment of a spheromorph, 310 μm in diameter.

Materials.—One specimen in sample U6 240.2 m from the Mainoru Formation.

Unnamed form F
Figure 7.12

Description.—Large, 16 to 29 μm wide filament in a 72 μm x 171 μm smooth indented sheath.

Materials.—A single specimen in sample U5 437 m from the Mainoru Formation (Showell Creek Member).

Remarks.—This large filamentous fossil differs from other sheathed filamentous taxa by the indentation of the sheath and absence of septae in the filament, although these characters could be taphonomic. Other taxa, such as *Rugosoopsis*, can reach large diameters, but have a distinct transverse fabric not observed here. *Palaeolyngbya* may also have a wide sheath, but is characterized by regular uniseriate array of well-preserved cells (Butterfield et al., 1994).

Discussion

Paleoecology: the distribution of Roper fossils in space.—Abbott and Sweet (2000) interpreted Roper sequence stratigraphy in terms of four facies groups: (1) paralic to fluvialite redbeds characterized by heterolithic, iron-rich sandstones along with finer siliciclastics and oolitic ironstone, dessication cracks and paleosols; (2) tide-dominated shoreline sandstones dominated by trough cross-bedded quartz arenite; (3) shore-face to storm-dominated shelf deposits with alternating rippled and cross-bedded quartz arenites and laminated siltites and shales; and (4) basinal facies consisting of thinly laminated shales deposited below storm wave base. In a preliminary study, Javaux et al. (2001) suggested that Roper diversity peaked in coastal facies, and analysis of the entire sample suite confirms this view. Microfossils do not occur in tidal sandstones and ironstones, but are abundant in shaley intervals of shoreface and

proximal shelf successions. Indeed, diversity is highest in shallow shelf environments characterized by interbedded shales and cross-bedded sandstones, with individual taxa peaking in abundance at different points along the shelf gradient (Fig. 8).

Eukaryotes and probable eukaryotes are least abundant and diverse in basinal shales throughout the Roper succession, the exception being *Blastanosphaera kokkoda*, which locally forms a monospecific assemblage in basinal shales, and rare *Dictyosphaera*. It has long been apparent empirically that quality of microfossil preservation varies inversely with total organic content (Butterfield et al., 1994). Therefore the limited presence of eukaryotes in basinal shales could reflect, in part, the high organic content of many basinal samples. That noted, even where basinal shales contain reasonably preserved microfossils, diversity is low. Bitumens occur throughout the Roper Group, in part the result of migration from source beds in the Velkerri Formation (Jackson and Raiswell, 1991; Dutkiewicz et al., 2003). Biomarker analysis of carbonaceous shales in the underlying McArthur Group suggests strong dominance of open water primary production by bacteria, including anoxygenic photosynthetic bacteria that inhabited anoxic waters within the photic zone (Brocks et al., 2005).

Biostratigraphy: the distribution of Roper fossils in time.—Early work in Russia established a broad biostratigraphic framework for organic-walled microfossils in Proterozoic shales, with *Satka favosa* characterizing early Mesoproterozoic samples and *Valeria lophostriata* more common in Neoproterozoic successions (summaries in Jankauskas et al., 1989; Sergeev et al., 2010). More recent research shows that both of these morphospecies co-occur with *Tappania plana* and other Roper taxa in the Kamo Group, Siberia, and in correlative shales of the Debengda Formation (Nagovitsin, 2009; Stanevich et al., 2009; Nagovitsin et al., 2010). The fossiliferous shales are interspersed with stromatolitic carbonates and so represent shallow platform environments. Depositional age is constrained only broadly by shale dating techniques to be ca. 1000–1500 Myr. Another possible Mesoproterozoic index fossil includes *Lineaforma* from the Roper Group, the Kotuikan Formation of Siberia (Vorob'va et al., 2015), and Belt Supergroup of Montana, USA (Adam, 2014).

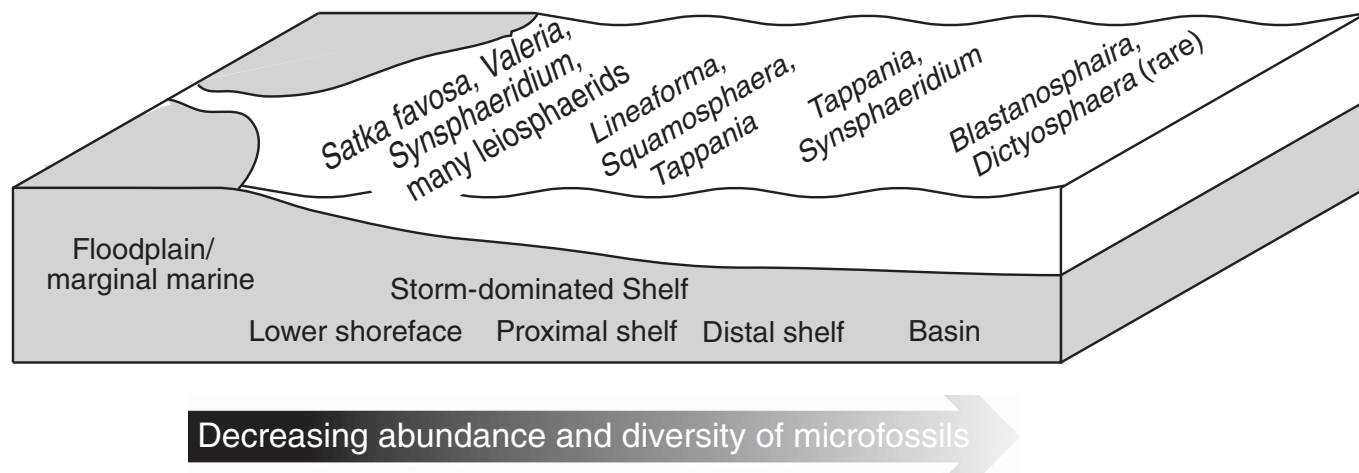

Figure 8. Paleogeological distribution of selected microfossils in the Roper Group.

Tappania plana occurs as well in the Ruyang Group, China (Xiao et al., 1997; Yin, 1997; Yin et al., 2005); the Sarda Formation of the Bahraich Group, Ganga Basin (Prasad and Asher, 2001) and possibly correlative beds of the Kheinjua Group, Vindhyan Basin (Prasad et al., 2005) in northern India; and in the Lower Belt Group, Montana (Adam, 2014; Adam et al., 2016). Detrital zircons indicate that Ruyang deposition began no earlier than 1700 Ma (Hu et al., 2014), and xenotime Pb-Pb ages of about 1400 Ma for the overlying Luoyu Group constrain deposition from above (Lan et al., 2014). A U-Pb zircon date from an ash bed within the Luoyu Group potentially constrains Ruyang deposition to be older than 1611 ± 8 Ma, but the abundance of detrital grains in the dated bed and the wide range of ages for individual zircons (Su et al., 2012) suggest that the published date may provide only a maximum age constraint on Luoyu deposition (Lan et al., 2014). Belt microfossils, which share many taxa in common with the Roper Group (Horodyski, 1980, 1993; Adam, 2014; Adam et al., 2016), are similarly constrained by a 1576 ± 13 Ma basement, 1460–1470 Ma sills that intrude into the fossiliferous stratigraphy and a U-Pb zircon date of 1454 ± 9 Ma for bentonite in the overlying Helena Formation (Lydon, 2007). U-Pb zircon dating of ash beds just below the Vindhyan succession containing unambiguous *Tappania* indicates that these fossils are $\leq 1631 \pm 1$ Ma (Ray et al., 2002). Thus, all known occurrences of *T. plana* fall within the latest Paleoproterozoic or Mesoproterozoic Era, with the Roper and Belt populations being the most tightly constrained by radiometric ages. The absence in Roper assemblages of distinctive taxa (e.g., the distinctive acanthomorphic taxon *Shuiyousphaeridium macroreticulatum* or the ornamented forms *Miroedichia* sp. and *Lophosphaeridium* sp.) that co-occur with *Tappania* elsewhere could reflect differences in either age or environment (e.g., Nagovitsin et al., 2010).

More broadly, the moderately diverse protist compressions of the Roper Group are intermediate in nature between the simple leiosphere-dominated assemblages found in most late Paleoproterozoic shales (e.g., Lamb et al., 2009; Peng et al., 2009) and the slightly more diverse (and taxonomically distinctive) assemblages reported from late Mesoproterozoic shales (e.g., Hermann, 1990; Samuelsson et al., 1999). Recently, Vorob'eva et al. (2015) reported a relatively diverse assemblage of microfossils in the ~1.5 Ga Kotuikan Formation of Siberia. The assemblage includes 12–14 spheroidal and filamentous forms plausibly interpreted as eukaryotes, but no acanthomorphs. Notably, the Kotuikan assemblage contains the distinctively striated filament *Lineaforma elongata*, which is also found in the Roper Group. Sergeev et al. (2016) also reported well-preserved microfossils in shales of the 1.4–1.45 Ga Kaltasy Formation, East European Platform, Russia. This assemblage includes a number of probable eukaryotic taxa, but also lacks conspicuously ornamented spheromorphic populations, which in this case possibly reflects the unusual (for Mesoproterozoic successions) combination of basinal deposition and oxic bottom waters. In general, then, the summed occurrences suggest that while many of the organic-walled microfossils in the Roper and other assemblages have long stratigraphic ranges, some can be used to identify uppermost Paleoproterozoic and Mesoproterozoic sedimentary successions and may, in time, permit the broad subdivision of Mesoproterozoic time.

The phylogenetic and functional interpretation of Roper fossils.—Because Roper fossils are both unusually well preserved and differentially well constrained by age and environment, they prompt questions of phylogenetic affiliation. In particular, can individual populations be identified with confidence as eukaryotes and, if so, can they further be assigned to extant eukaryotic clades?

In principle, Roper populations could include the polysaccharide sheaths and envelopes of cyanobacteria or other bacteria, the walls of metabolically active eukaryotic cells, and eukaryotic resting or reproductive cysts. Cyst walls are commonly reinforced with compounds that improve preservation potential, for example, sporopollenin in plant spores, dinosporin in some dinoflagellates, and algaenan in a few green algae and eustigmatophytes (de Leeuw et al., 2006; Kodner et al., 2009; Scholz et al., 2014). Known and assumed protistan cysts predominate in Phanerozoic marine shales, and this has understandably influenced the interpretation of older microfossils. We must recognize, however, that prospects for the preservation of vegetative walls would have been enhanced in the low-oxygen, bioturbation-free muds found widely in earlier seaways, as illustrated by the preservation of simple multicellular and coenocytic remains in Neoproterozoic shales (Butterfield et al., 1994; Butterfield, 2009) and carbonaceous seaweeds in Ediacaran and Paleozoic successions (e.g., Xiao et al., 2002; LoDuca et al., 2003; Kenrick and Vinther, 2006; Yuan et al., 2011).

Bacterial microfossils do occur in the Roper assemblage, especially *Siphonophycus* spp., which is found as minor components of Roper assemblages. Sheath-forming filaments occur in a number of bacterial clades, but given their relatively large size and occurrence in oxic waters within the shallow reaches of the photic zone, *Siphonophycus* populations are most readily interpreted as cyanobacteria comparable to modern *Lyngbya*, *Plectonema*, and *Phormidium* (Rippka et al., 1979). The Roper assemblage also includes rare trichomes and pseudoseptate filaments that may record cyanobacteria or other bacteria. Such an interpretation is fully in accord both with microfossil assemblages preserved in Proterozoic cherts and molecular clocks that indicate major cyanobacterial diversification before the time of Roper deposition (Tomitani et al., 2006, and references cited therein).

Cyanobacteria may also occur among spheromorphic forms. Horodyski (1993), for example, interpreted *Satka squamifera* as possible envelopes of colonial entophysalid cyanobacteria, a view formalized by the reassignment of this and other probable synonyms of *Satka colonialica* to *Squamosphaera* (Tang et al., 2015; Porter and Riedman, in press). Simple leiosphaerid compressions could also include the envelopes of colonial coccoidal cyanobacteria, some of which can have both a large diameter and medial splits similar to those commonly interpreted as excystment structures in microfossils (Waterbury and Stanier, 1978). TEM may be necessary to ascertain the affinities of leiosphaerids, especially those with very thin walls. In the limited number of Roper specimens examined to date, preserved complex multilayered wall ultrastructure suggests eukaryotic rather than cyanobacterial affinities (Javaux et al., 2004; see systematic paleontology section).

While comparisons to cyanobacteria are based principally on morphological similarities, constrained by paleoenvironmental setting (e.g., Knoll and Golubic, 1992), taphonomic experiments underscore the preservation potential of cyanobacterial sheaths and envelopes (e.g., Bartley, 1996). Recent microanalyses of modern and subfossil mats in Antarctic lakes provide strong evidence for the preservation of cyanobacterial morphologies and chemistries, including sheaths and the sheath pigment scytonemin (Lepot et al., 2014).

If eukaryotic, Roper microfossils must be viewed as the remains of cell walls, which places both functional and phylogenetic constraints on interpretation. Cell walls are best known from algae, especially the cellulosic cell walls of green, red, brown, dinoflagellate, and some golden-brown algae (Graham and Wilcox, 2000). Walls occur, as well, in osmotrophic eukaryotes, including the chitinous walls of fungi and the cellulosic walls of oomycetes (Melida et al., 2013). Moreover, a wall can form during a specific life cycle stage, even in organisms not otherwise characterized by cell wall synthesis (e.g., the cellulosic macrocyst walls of dictyostelid amoebozoans) (Saga and Yanagisawa, 1982; Blanton et al., 2000) and chemically uncharacterized walls synthesized by coccoidal cells in chlorarachniophyte rhizarians (Ishida and Hara, 1994).

Walled resting or reproductive cysts occur widely within the Eukarya, not only in algae, but also in heterotrophic clades. Ciliates, for example, make cyst walls that can be smooth or conspicuously ornamented (Beers, 1948, 1966; Foissner et al., 2007; Verni and Rosati, 2011), and so do many animals (e.g., Blades-Eckelbarger and Marcus, 1992). In many eukaryotes, cyst formation (commonly but not always associated with sexual fusion) is induced by conditions that inhibit growth, including desiccation, nutrient deprivation, and anoxia, and so one might expect a resting stage to occur in the life cycles of eukaryotes in oceans with anoxic water masses beneath a thin oxic mixed layer (Johnston et al., 2012). The broad phylogenetic distribution of cellulose and other wall compounds suggests that the ability to synthesize a protective wall evolved early in the Eukarya, perhaps before the earliest divergences of crown group taxa.

Tappania plana has been interpreted as a metabolically active microorganism on the basis of its irregularly placed, occasionally branching processes that extend outward from the main vesicle (Xiao et al., 1997; Javaux et al., 2003, 2004). Bulbous extensions on the same individuals may record vegetative reproduction. Cell walls that completely encompass individuals are common in photosynthetic and osmotrophic eukaryotes, but the cylindrical extensions provide a functional argument in favor of osmotrophy. These structures would increase the surface area for absorption and enable cells to probe nutrient-rich habitat patches, but would do little to enhance primary production. Butterfield (2005a), in fact, interpreted *Tappania* as a possible fungus, based on a population from Neoproterozoic shales of the Shaler Group, the Canadian Arctic (but see Butterfield, 2015). As noted in the systematic paleontology section, Shaler fossils differ in many ways from Roper and other Mesoproterozoic *Tappania*, but the functional argument holds. In eukaryote evolution, phagotrophy is the ancestral state (evolved at least at the time of LECA, Knoll and

Lahr, 2016), while phototrophy required the evolution of chloroplast by endosymbiosis of a cyanobacteria, and thus is derived and evolved not later than 1.1 Ga—the age of *Bangiomorpha*. Today, many marine protists are mixotrophs (able to use both phagotrophy and phototrophy; Mitra et al., 2016).

The ability to absorb dissolved organic molecules (osmotrophy) is ubiquitous among protists (Mitra et al., 2016), but only a few clades, chiefly fungi and oomycetes, employ osmotrophy as the primary or sole means of obtaining food, having lost phagotrophy (Richards and Talbot, 2013). Recently, Knoll and Lahr (2016) investigated the phylogenetic distribution of major feeding modes within the Eukarya. While bacterivory is basal within the domain, other feeding modes evolved early, helping to explain the later Mesoproterozoic diversification of crown groups. Molecular clock estimates for the initial divergence of crown group fungi generally postdate Roper time (e.g., 800 Ma, Berney and Pawlowski, 2006; 730–820 Ma, Lücking et al., 2009; 1050 Ma, Parfrey et al., 2011; 812 Ma, Floudas et al., 2012). Crown group Stramenopiles may also have late Mesoproterozoic or Neoproterozoic origins (e.g., Parfrey et al., 2011). For this reason, it is possible that early Mesoproterozoic *Tappania* fossils record stem group protists functionally, but not necessarily phylogenetically comparable to extant osmotrophic heterotrophs. In any event, the complex morphology of *Tappania* provides direct evidence for cell organization by a dynamic cytoskeleton and membrane system, which is a fundamental feature of eukaryotic biology (Javaux et al., 2001; Knoll et al., 2006).

Other Roper fossils find reasonable interpretation as cyst walls, for example, *Valeria lophostriata*, with its distinctive ornamentation of parallel ridges and opening by medial split (Javaux et al., 2003, 2004). Accepting *V. lophostriata* as a resting or reproductive cyst relaxes any constraint on its metabolism or placement within a specific subgroup of the eukaryotic domain (as noted above, cysts occur in many eukaryotic taxa that lack walls on metabolically active cells). Similarly, the ornamented spheromorphs *Dictyosphaera delicata*, with its reticulated wall, and *Satka favosa*, with its wall made of polygonal plates and (rare) opening by medial split, are best interpreted as eukaryotic cysts. *Blastanosphaera kokkoda* has a finely chagrinate wall, and intensive budding, both of which are evidence for vegetative reproduction.

Spheromorphic microfossils in Paleo- and Mesoproterozoic rocks have sometimes been interpreted as green algae, requiring an early origin of photosynthesis in the domain (Moczyłowska et al., 2011). Chlorophyte algae are sometimes recognized on the basis of a distinctive trilaminar structure (TLS) observed in TEM images of cell walls (Allard and Templier, 2000), and TLS has been documented in microfossils as old as Cambrian (Talyzina and Moczyłowska, 2000). TLS covaries phylogenetically with the biosynthetic capacity to make long-chain aliphatic molecules called algaenans (Allard and Templier, 2000), and a phylogenetic survey of this capacity suggests that it may be limited to two (now) non-marine clades within the Trebouxiophyceae and Chlorophyceae (Kodner et al., 2009), neither of which is likely to have diverged much earlier than the Ediacaran or Cambrian periods. In the Roper Group's taxa studied with

Figure 9. Comparison of Roper age with molecular clock estimates for the divergences of crown group green algae, photosynthetic eukaryotes, and crown group eukaryotes. Circle, diamond and triangles are the mean ages for the origin of crown group algae, plastid, crown group eukaryotes, respectively, and the dark gray, medium gray and white rectangles represent the errors on estimates, respectively.

TEM, the occurrence of TLS has not been observed to date and we have no indication for photosynthetic eukaryotic crown group taxa (Javaux et al., 2004).

Alternatively, prasinophyte algae, a paraphyletic group at the base of the green algal tree, can form thick-walled phycmata, which are found widely in Paleozoic shales (Colbath and Grenfell, 1995). Some phycmata have a diagnostic ultrastructure (Talyzina and Moczyłowska, 2000), but this has not been observed in Roper or other microfossils of comparable age. Thus, the argument that Roper and other early microfossil assemblages contain green algae must rely on broad comparisons of simple morphologies and the debatable assumption that preserved eukaryotic microfossils are likely to be algal.

Molecular estimates for the origin of crown group green algae vary widely (Fig. 10), but generally suggest late Mesoproterozoic or younger diversification (e.g., 1100 Ma, Heckman et al., 2001; 1200 Ma, Yoon et al., 2004; 1000–900 Ma, Parfrey et al., 2011; 936 Ma, Becker, 2013; and even ~700 Ma, Berney and Pawlowski, 2006). The ~800 Ma *Cladophora*-like fossil *Proterocladus* casts doubt on the youngest molecular clock estimates, and the early diverging red alga *Bangiomorpha* from 1100–1200 Ma cherts in the Canadian Arctic (Butterfield, 2000) further constrains the age of total (but not crown) group green algae. Nonetheless, if

even the oldest of current molecular clock estimates is broadly correct, it is unlikely that Roper microfossils can be interpreted in terms of specific extant clades within the green algae.

If Roper leiosphaerids cannot be assigned to crown group green algal clades, what are the possibilities for phylogenetic placement? Not surprisingly, age estimates for the last eukaryotic common ancestor (LECA) of all extant eukaryotes vary among treatments, but those not rejected on the basis of *Bangiomorpha*'s age and interpretation suggest a late Paleoproterozoic or early Mesoproterozoic time of origin for the eukaryotic crown group (Fig. 9). Accepting this, Roper fossils could include the vegetative walls or resting cysts of stem-group green algae, stem-group taxa of the more inclusive Archaeplastida (green algae/embyrophytes, red algae and glaucocystophytes, united by the presence of a chloroplast derived via primary endosymbiosis with a cyanobacterium), stem-group or morphologically unrecognizable crown-group members of other non-photosynthetic eukaryotic clades, or stem-group eukaryotes (before LECA). In the absence of additional data, we find it impossible to choose among these possibilities. Note, however, that it would not be unusual to have a biota dominated by stem-group members of a clade. For example, most arthropod diversity in early and mid-Cambrian oceans belonged to stem group members of the phylum, and the same is true of

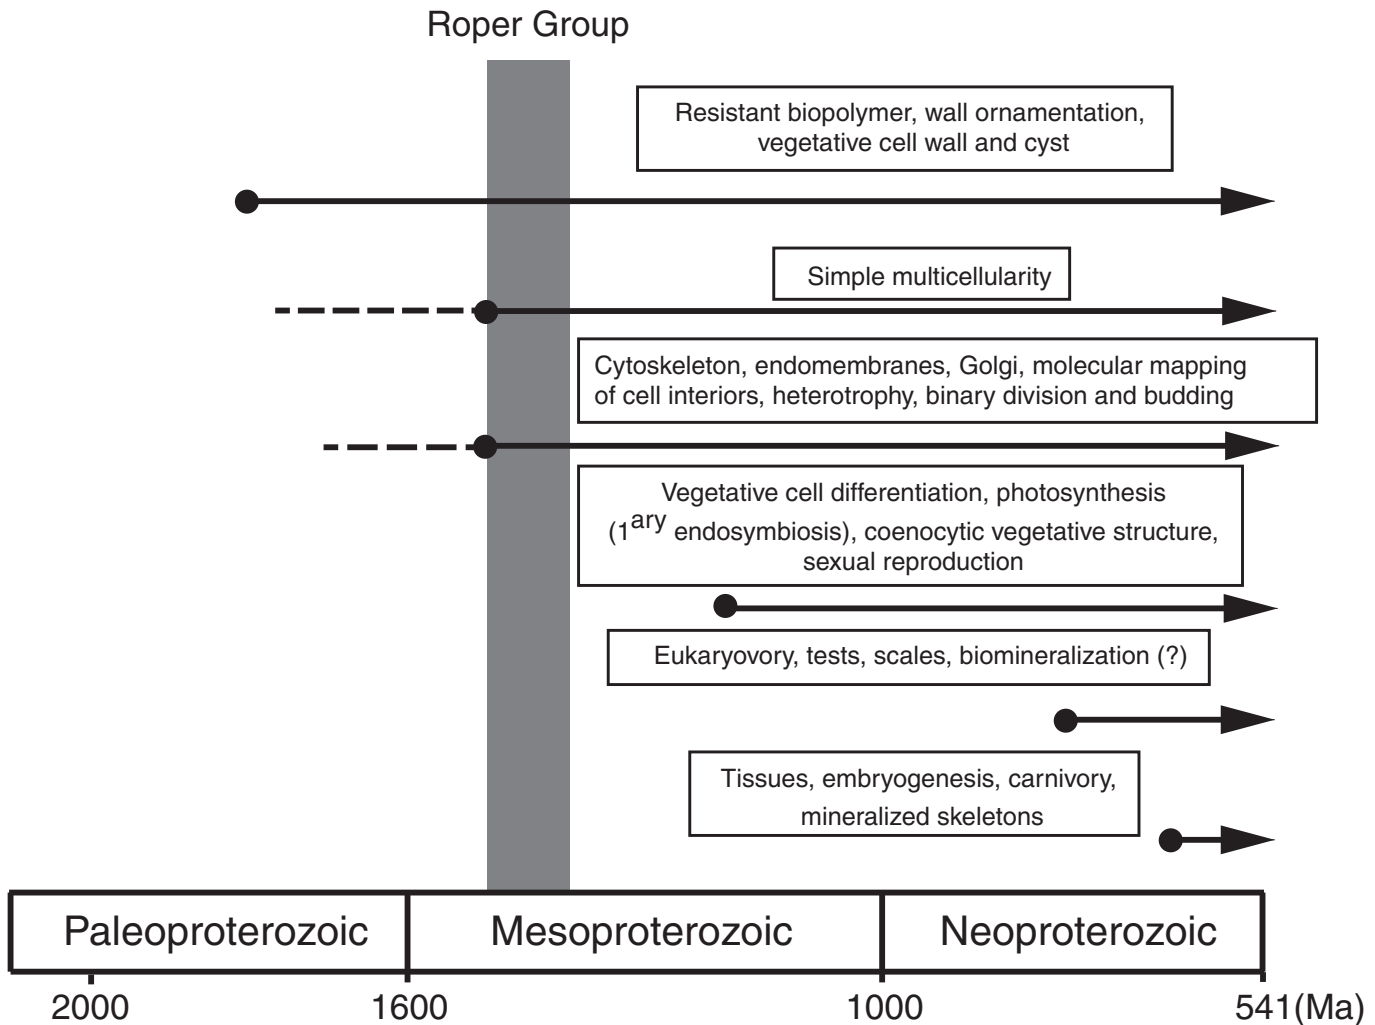

Figure 10. Biological innovations in early eukaryotes inferred from preserved microfossils (modified from Javaux, 2011).

Cambrian echinoderms, Carboniferous seed plants, and many other clades. Stem-group taxa are common in the deep fossil record.

Finally, there are the large, striated tubes of *Lineaforma elongata*, which commonly are fragmental but locally abundant in Roper samples. The size and complexity of these tubes favor a eukaryotic interpretation, but more specific attribution is impossible.

In general, then, eukaryotic remains are prominent, even dominant components of the Roper assemblage, but all are simple and, at lower taxonomic levels, problematic. Consistent with molecular clock inferences, Roper eukaryotes may include stem-group taxa; early, morphologically unattributable crown-group species; or both. Missing from the Roper biota are highly ornamented cysts of the type found commonly in later Neoproterozoic and, especially, Phanerozoic shales. Cyst ornamentation can serve a number of purposes (see, for example, Cohen et al., 2009), one of which is defense against predation (e.g., Peterson and Butterfield, 2005). The last common ancestor of extant eukaryotes was probably a heterotroph capable of phagocytosing bacteria and other small particles; eukaryotes that eat other eukaryotic cells, however,

are derived (Knoll and Lahr, 2016). The limited ornamentation of Roper microfossils is consistent with the hypothesis that predation on protists was low prior to the Neoproterozoic Era, because of the relatively late radiation of eukaryovorous protists (Knoll, 2014) and animals (Butterfield, 2015).

Taxonomy aside, the Roper assemblage documents biological innovations in early eukaryotes (Fig. 10; see also Javaux, 2006, 2011; Knoll et al., 2006). Reproductive modes in Roper populations include simple binary division and budding (e.g., *Tappania*, *Blastanosphaira*). We have no direct evidence for sex in Roper populations, but this reflects absence of evidence and not necessarily evidence of absence. Sex was present in the last common ancestor of extant eukaryotes, so any paleontological inference must rest on currently uncertain systematic interpretations of Roper fossils as stem- or crown-group eukaryotes. Whether associated with sexual fusion or not, Roper protists formed resting cysts, with excystment by medial split (*Valeria*, *Satka favosa*) and possibly by the opening of neck-like expansions (*Tappania*). Simple multicellularity is observed both in eukaryotes (septa in *Tappania* processes) and in prokaryotes (colonies of diverse types and filaments). The wall ornamentation of several taxa, especially *Tappania*'s

heteromorphic processes and the plates of *Satka favosa* and *Dictyosphaera delicata*, implies the presence of a eukaryotic cytoskeleton. The tessellation of organic plates to make up the wall of these acritarchs further suggests the presence of an internal membrane system (including endoplasmic reticulum, or ER) and Golgi apparatus. The Golgi apparatus (or remnants of, in parasites) and the ER are essential for intracellular transport, occur in all extant eukaryotes, and are associated with the nuclear envelope (Jékely, 2006), although the relative timing of their appearance is unknown and the origin of the nucleus itself is far from constrained (see review in Lopez-Garcia and Moreira, 2015).

Conclusions

Roper microfossils contribute to an increasingly refined picture of life in Mesoproterozoic oceans, complementing the window opened by microfossils preserved in silicified carbonates. Chert assemblages largely illuminate peritidal environments dominated by diverse cyanobacteria and contain few recognizable eukaryotes (Muir, 1976, 1979; Oehler, 1978; Horodyski and Donaldson, 1980, 1983; Zhang, 1981; Golubic et al., 1995; Sergeev et al., 1995).

Stromatolites further indicate that microbial mat communities covered extensive portions of the Mesoproterozoic seafloor, extending from supratidal environments to the base of the photic zone (Bertrand-Sarfati and Walter, 1981; Walter et al., 1988). Cyanobacteria are generally accepted as the principal architects of Mesoproterozoic stromatolites, but whether eukaryotes participated in mat communities is difficult to know, given that few stromatolites contain well-preserved microfossils. Variation in macrostructure may well tell us mostly about the range of physical and chemical environments in which stromatolites accreted (e.g., Grotzinger and Knoll, 1999; Bosak et al., 2013), but microstructure, or petrofabric, can preserve clues to microbial community diversity (Knoll et al., 2013). Eukaryotes could be recorded by macroscopic chain-of-beads impressions called *Horodyskia* (Grey and Williams, 1990; Fedonkin and Yochelson, 2002; review in Dong et al., 2008) and the Mesoproterozoic specimens of coiled centimeter-scale septate compressions named *Grypania* (Walter et al., 1990), both exposed on siliciclastic bedding planes. The phylogenetic and functional nature of these organisms remains obscure.

Microfossils suggest that eukaryotic organisms were most common in the water column and non-mat benthos of well-oxygenated, shallow-shelf environments. Because the last common ancestor of extant eukaryotes was a phagocytosing heterotroph that consumed bacteria and other small particles, Roper eukaryotes certainly would have played a role in completing the marine carbon cycle. This may have been true in anoxic as well as oxic environments, because many eukaryotes retain the capacity for anaerobic metabolism (Müller et al., 2012). Osmotrophic uptake of organic molecules must also have occurred, and appears to have the primary form of carbon acquisition in *Tappania plana*. As discussed above, phagotrophic protists were present in Mesoproterozoic oceans, but these may not have included protists able to eat other large eukaryotic cells.

Whether eukaryotes played an important role as primary producers is less clear. As noted above, microfossil morphologies are agnostic with respect to this metabolism, and limited organic geochemical data suggest that bacteria were the principal primary producers in Mesoproterozoic oceans (Brocks et al., 2005). Primary production by eukaryotes might well have been limited by fixed nitrogen availability (Anbar and Knoll, 2002; Reinhard et al., 2013), especially in oxic waters above sulfidic water masses (Boyle et al., 2013). The spatial distribution of presumed eukaryotes in the Roper Basin is consistent with isotopic inferences about Mesoproterozoic nitrogen cycling (Stüeken, 2013). Upward mixing of anoxic and sometimes sulfidic waters would also have constituted a persistent challenge for eukaryotes in the photic zone (Johnston et al., 2009, 2010; Guilbaud et al., 2015).

In short, Mesoproterozoic oceans supported diverse microbial communities that included early eukaryotes, some of them preserved in Roper shales. The diversity and ecological importance of these early protists, however, were much lower than in later Neoproterozoic and Phanerozoic ecosystems, which is a function, at least in part, of ecological constraints involving food web complexity and physical constraints imposed by marine redox profiles.

Acknowledgments

We thank M. Walter and the core facility staffs at the Northern Territory Geological Survey in Darwin and the Australian Geological Survey Organization in Canberra for making it possible to sample Roper cores. We also thank Z. Adam, V.N. Sergeev, L.A. Riedman, and S. Porter for discussion and access to unpublished materials, and reviewers for helpful criticisms of an earlier draft. E.J. acknowledges support from European Research Council Stg ELITE FP7/308074, Belspo IAP Planet Topers, and the Francqui Foundation research professorship. AHK acknowledges support from NASA Exobiology Grant NAG5-3645 and the NASA Astrobiology Institute.
