Flavonoid Apigenin Is an Inhibitor of the NAD⁺ase CD38
Implications for Cellular NAD⁺ Metabolism, Protein Acetylation, and Treatment of Metabolic Syndrome

Carlos Escande,¹ Veronica Nin,¹ Nathan L. Price,² Verena Capellini,¹ Ana P. Gomes,² Maria Thereza Barbosa,¹ Luke O’Neil,¹ Thomas A. White,¹ David A. Sinclair,² and Eduardo N. Chini¹

Metabolic syndrome is a growing health problem worldwide. It is therefore imperative to develop new strategies to treat this pathology. In the past years, the manipulation of NAD⁺ metabolism has emerged as a plausible strategy to ameliorate metabolic syndrome. In particular, an increase in cellular NAD⁺ levels has beneficial effects, likely because of the activation of sirtuins. Previously, we reported that CD38 is the primary NAD⁺ase in mammals. Moreover, CD38 knockout mice have higher NAD⁺ levels and are protected against obesity and metabolic syndrome. Here, we show that CD38 regulates global protein acetylation through changes in NAD⁺ levels and sirtuin activity. In addition, we characterize two CD38 inhibitors: quercetin and apigenin. We show that pharmacological inhibition of CD38 results in higher intracellular NAD⁺ levels and that treatment of cell cultures with apigenin decreases global acetylation as well as the acetylation of p53 and RelA-p65. Finally, apigenin administration to obese mice increases NAD⁺ levels, decreases global protein acetylation, and improves several aspects of glucose and lipid homeostasis. Our results show that CD38 is a novel pharmacological target to treat metabolic diseases via NAD⁺-dependent pathways. Diabetes 62:1084–1093, 2013

Obesity is a disease that has reached epidemic proportions in developed and developing countries (1–3). In the U.S., >60% of the population is overweight (1,4). Obesity is a feature of metabolic syndrome, which includes glucose intolerance, insulin resistance, dyslipidemia, and hypertension. These pathologies are well-documented risk factors for cardiovascular disease, type 2 diabetes, and stroke (4). It is therefore imperative to envision new strategies to treat metabolic syndrome and obesity.

Recently, the role of NAD⁺ as a signaling molecule in metabolism has become a focus of intense research. It was shown that an increase in intracellular NAD⁺ levels in tissues protects against obesity (5,6), metabolic syndrome, and type 2 diabetes (5–7). Our group was the first to demonstrate that an increase in NAD⁺ levels protects against high-fat diet–induced obesity, liver steatosis, and metabolic syndrome (5). This concept was later expanded by others using different approaches, including inhibition of poly-ADP-ribose polymerase (PARP)1 (6) and stimulation of NAD⁺ synthesis (7).

The ability of NAD⁺ to affect metabolic diseases seems to be mediated by sirtuins (8). This family of seven NAD⁺-dependent protein deacetylases, particularly SIRT1, SIRT3, and SIRT6, has gained significant attention as candidates to treat metabolic syndrome and obesity (9). Sirtuins use and degrade NAD⁺ as part of their enzymatic reaction (8), which makes NAD⁺ a limiting factor for sirtuin activity (9).

In particular, silent mating information regulation 2 homolog 1 (SIRT1) has been shown to deacetylately several proteins, including p53 (10), RelA/p65 (11), PGC1-α (12), and histones (13), among others. In addition, increased expression of SIRT1 (14), increased SIRT1 activity (15), and pharmacological activation of SIRT1 (16) protect mice against liver steatosis and other features of metabolic syndrome when mice are fed a high-fat diet. Given the beneficial consequences of increased SIRT1 activity, great efforts are being directed toward the development of pharmacological interventions aimed at activating SIRT1.

We previously reported that the protein CD38 is the primary NAD⁺ase in mammalian tissues (17). In fact, tissues of mice that lack CD38 contain higher NAD⁺ levels (17,18) and increased SIRT1 activity compared with wild-type mice (5,17). CD38 knockout mice are resistant to high-fat diet–induced obesity and other aspects of metabolic disease, including liver steatosis and glucose intolerance, by a mechanism that is SIRT1 dependent (5). These multiple lines of evidence suggest that pharmacological CD38 inhibition would lead to SIRT1 activation through an increase in NAD⁺ levels, resulting in beneficial effects on metabolic syndrome.

Recently, it was shown that in vitro, CD38 is inhibited by flavonoids, including quercetin (19). Flavonoids are naturally occurring compounds present in a variety of plants and fruits (20). Among them, quercetin [2-(3,4-dihydroxyphenyl)-3,5,7-trihydroxy-4H-chromen-4-one] and apigenin [5,7-dihydroxy-2-(4-hydroxyphenyl)4H-1-benzopyran-4-one] have been shown to have beneficial effects against cancer (21–24). In fact, apigenin and quercetin ameliorate atherosclerosis (25) and reduce inflammation (26–28). However, the mechanisms of action of flavonoids remain largely unknown. We hypothesized that the effect of some flavonoids in vivo may occur through inhibition of CD38 and an increase in NAD⁺ levels in tissues, which lead to protection against metabolic syndrome.

Here, we show that CD38 expression and activity regulate cellular NAD⁺ levels and global acetylation of proteins, including SIRT1 substrates. We confirmed that quercetin is a CD38 inhibitor in vitro and in cells. Importantly, we
demonstrate that apigenin is a novel inhibitor of CD38 in vitro and in vivo. Treatment of cells with apigenin or quercetin inhibits CD38 and promotes an increase in intracellular NAD⁺ levels. An increased NAD⁺ level decreases protein acetylation through sirtuin activation. Finally, treatment of obese mice with apigenin results in CD38 inhibition, higher NAD⁺ levels in the liver, and a decrease in protein acetylation. Apigenin treatment improves glucose homeostasis, glucose tolerance, and lipid metabolism in obese mice. Our results clearly demonstrate that CD38 is a novel therapeutic target for the treatment of metabolic diseases and that apigenin and quercetin as well as other CD38 inhibitors may be used to treat metabolic syndrome.

RESEARCH DESIGN AND METHODS

Reagents and antibodies. All reagents and chemicals were from Sigma-Aldrich. Antibodies for human SIRT1, mouse SIRT1, p65, acetylated p53 (K382), phosphorylated AMP-activated protein kinase (AMPK) (Thr172), AMPK, and acetyl-lysine were from Cell Signaling Technology. Antibody against Nampt was from Bethyl Laboratories, and anti-mouse CD38 was from Epitomics.

Cell culture. A549 cells were kept in RPMI 1640 media supplemented with 10% FBS and penicillin/streptomycin (Invitrogen). Primary CD38 wild-type and knockout mouse embryonic fibroblasts (MEFs) were kept in Dulbecco’s modified Eagle’s medium supplemented with 10% FBS and penicillin/streptomycin. Overexpression and small interfering RNA. Full-length human CD38 was subcloned into a modified pIRE2-enhanced green fluorescent protein vector. For overexpression, 293T cells were transfected for 48 h with Lipofectamine 2000 (Invitrogen) following the manufacturer’s instructions.

For CD38 knockdown experiments, probe no. 2 of a TriFECTa kit against human CD38 was used (cat. no. HSC.RNAI.N001775.12.2; IDT). A549 cells were transfected with 40 nmol small interfering RNA (siRNA) duplex using Lipofectamine 2000 according to the manufacturer’s instructions.

Determination of CD38 activity. Determination of CD38 activity in cells and tissues was performed as previously described (17). In vitro CD38 activity was measured using 0.1 unit of recombinant human CD38 (R&D Systems) in 0.25 mol/L sucrose and 40 mmol/L Tris-HCl (pH 7.4). The reaction was started by addition of 0.2 mmol/L substrate. Nicotinamide 1,N⁶-ethenoadenine dinucleotide was used to determine NAD⁺ase activity and nicotinamide guanine dinucleotide to determine cyclase activity. CD38 activity was expressed as arbitrary fluorescent units per minute (AFU/min).

NAD⁺ quantification. NAD⁺ extraction and quantification was performed as previously described (17). In brief, cells were lysed by sonication in ice-cold 10% trichloroacetic acid, and then the trichloroacetic acid was extracted with two volumes of an organic phase consisting of 1,1,2-trichloro-1,2,2-trifluoroethane and trioctylamine. NAD⁺ concentration was measured by means of an enzymatic cycling assay (18).

FIG. 1. CD38 overexpression decreases NAD⁺ and promotes protein acetylation in cells. 293T cells were transfected with empty vector or human CD38-coding vector. After 48 h, cells were harvested, and NAD⁺ase activity (A), ADP-ribosyl-cyclase activity (B), and total intracellular NAD⁺ levels (C) were measured in cell lysates. *P < 0.05, n = 3. D: Western blot for CD38 in 293T cells transfected with empty vector or with human CD38. E: Western blot showing total protein acetylation in cells transfected with empty vector or with human CD38. Anti–acetylated (Ac) lysine antibody was used. Red arrows highlight the main bands that showed variations in intensity. F: Intensity profile of the Western blot shown in E. Western blots were scanned and intensity profile was obtained using ImageJ. Red arrows correspond with intensity of the same bands shown in E.
Determination of SIRT1 activity. SIRT1 activity was measured with a fluorimetric assay (Enzo) as previously described (15). One unit of human recombinant SIRT1 was incubated with different concentrations of apigenin plus 100 μmol/L Fluor-de-Lys p53 tetra peptide and 100 μmol/L NAD+. Fluor-de-Lys developer was prepared according to the manufacturer's recommendations and added to the reactions for 1 h. Fluorescence was read with an excitation of 360 nm and emission at 460 nm.

Mouse studies. All mice used in this study were maintained in the Mayo Clinic Animal facility. All experimental protocols were approved by the institutional animal care and use committee at Mayo Clinic (protocol no. A33209), and all studies were performed according to the methods approved in the protocol. For generation of obese mice, twelve 20-week-old C57BL/6 mice were placed on a high-fat diet (AIN-93G, modified to provide 60% of calories from fat; Dyets) ad libitum for 4 weeks. Body weight was recorded weekly. After 4 weeks of high-fat diet, mice were randomly divided in two groups and injected daily with 100 mg/kg i.p. apigenin or vehicle for 7 consecutive days while remaining on the high-fat diet. During the treatments, food intake and body weight were monitored daily. There was no difference in these parameters between groups. For the glucose tolerance experiments, mice were housed for 24 h without food, but with water ad libitum, and challenged with one dose of 1.5 g/kg i.p. dextrose. Area under the curve was calculated by the net incremental method (with baseline) and presented as incremental area under the curve.

Gene expression analysis. RNA from flash-frozen liver tissue was extracted with an RNeasy Mini Kit (Qiagen) according to the manufacturer's instructions. cDNA was synthesized with the iScript cDNA synthesis kit (BioRad) using 600 ng RNA. Quantitative RT-PCR reactions were performed using 1 μmol/L primers and LightCycler 480 SYBR Green Master (Roche) on a LightCycler 480 detection system (Roche). Calculations were performed by a comparative method (2-ΔΔCT) using 18S rRNA as an internal control. Primers were designed using the IDT software, and the primer sequences were as follows: long-chain acyl-CoA dehydrogenase (LCAD), forward (Fw) GGTGAAAAACGGAATT GAAAAG, reverse (Rv) GGCAATGGGACACCTTTCAAG; medium-chain acyl-CoA dehydrogenase (MCAD), Fw GGGCATCATTTCTGG; CPT1a, Fw AGACAAAGACCCCAACATCC, Rv CAA AGGTGTCAAATGGGAAGG; and 18S, Fw CGGCTACCACTTTCCAGGG, Rv GCTGGAAATCTCCGGCCT.

Lipid treatment. Cells were incubated with a mixture of oleic acid and palmitic acid in a 2:1 ratio in culture media supplemented with 1% fatty acid–free BSA (Sigma-Aldrich). Lipids were used at concentrations shown to induce steatosis but not apoptosis (15). Incubations with lipids were performed for 16–24 h.

Statistics. Values are presented as means ± SEM of three to five experiments unless otherwise indicated. The significance of differences between means was assessed by ANOVA or two-tailed Student t test. A P value < 0.05 was considered significant.

RESULTS

CD38 overexpression decreases NAD⁺ and promotes protein acetylation. We have previously shown that CD38 is the primary NAD⁺ase in mammalian tissues (17).

FIG. 2. CD38 downregulation increases NAD⁺ and decreases protein acetylation in cells. A549 cells were transfected with a scrambled siRNA (control siRNA) or human CD38 siRNA. After 72 h, cells were harvested and NAD⁺ase activity (A), ADP-ribosyl-cyclase activity (B), and total intracellular NAD⁺ levels (C) were measured from cell lysates. *P < 0.05, n = 3. D: Western blot showing total protein acetylation in cells transfected with control siRNA or with human CD38 siRNA. Anti–acetylated (Ac) lysine antibody was used. Red arrows highlight the main bands that showed variations in intensity. E: Intensity profile of the Western blot shown in D. Western blots were scanned and intensity profile was obtained using Image J. Red arrows correspond with intensity of the same bands showed in D. F–H: Primary MEFs were purified and cultured from wild-type (WT) and CD38 knockout (KO) mice. F: Intracellular NAD⁺ levels (*P < 0.05, n = 3). G: Western blot from wild-type and CD38 knockout MEFs showing total protein acetylation in these cells. H: Representative Western blot in wild-type and CD38 knockout MEFs. Acetylated RelA/p65 (K310), total RelA/p65, SIRT1, CD38, and actin antibodies were used.
CD38-deficient mice have increased NAD⁺ levels in multiple tissues (5,17). To further characterize the role of CD38 in the regulation of NAD⁺-dependent cellular events, we studied the effect of CD38 manipulation in cells. We found that cells that overexpress CD38 show a significant increase in NAD⁺ase and ADP ribosyl cyclase activities (Fig. 1A and B) and a consistent decrease in intracellular NAD⁺ levels (Fig. 1C). Interestingly, we found that overexpression of CD38 also led to an increase in global protein acetylation (Fig. 1E). The pattern of acetylated proteins was analyzed by plotting an intensity profile of the lanes in the Western blots (Fig. 1F). It is worth noting that CD38 overexpression promotes changes in the level of acetylation of several proteins (red arrows in Fig. 1E and F), while other bands remain unchanged. This is consistent with the fact that only sirtuin deacetylases depend on NAD⁺ for their activity (8); histone deacetylases of classes I and II have a different enzymatic mechanism that does not require NAD⁺ (29).

**CD38 downregulation increases NAD⁺ and decreases protein acetylation.** Next, we examined whether CD38 downregulation promotes the opposite effect on cellular NAD⁺ levels and global protein acetylation. This is of key relevance, since we (5) and other investigators (6,7) have shown that an increase in intracellular NAD⁺ levels protects against metabolic diseases and aging. We transfected cells with control or CD38 siRNA. Cells treated with CD38 siRNA had decreased NAD⁺ase and ADP-ribosyl-cyclase activities (Fig. 2A and B) and a significant increase in intracellular NAD⁺ levels (Fig. 2C), consistent with the diminished CD38 NAD⁺ase activity. Moreover, the increase in NAD⁺ levels was accompanied by a decrease in global protein acetylation (Fig. 2D and E). Finally, we isolated primary MEFs from wild-type and CD38 knockout mice and measured NAD⁺ levels and protein acetylation. We found that CD38 knockout MEFs have increased NAD⁺ levels (Fig. 2F) and decreased global protein acetylation (Fig. 2G). We also analyzed p65/RelA acetylation at K310, a site that is an accepted target for cellular SIRT1 activity (7,11). We found that CD38 knockout MEFs show no detectable p65/RelA (K310) acetylation compared with wild-type cells, despite having similar total p65/RelA protein (Fig. 2H) and similar SIRT1 levels. This indicates that SIRT1 activity is increased in the CD38 knockout MEFs.

**Apigenin and quercetin inhibit CD38 activity in vitro.** By use of high-throughput analysis to search for inhibitors of CD38, we found that several flavonoids, including quercetin and apigenin, inhibit CD38 in vitro. The complete screen will be published elsewhere. Recently, Kellenberger et al. (19) also published a list of flavonoids that act as CD38 inhibitors in vitro, many of which were also confirmed by our analysis. Quercetin was one of the compounds found by Kellenberger et al. (19) to inhibit CD38 in vitro. Apigenin, however, was demonstrated to be a novel CD38 inhibitor. We proceeded to further characterize these compounds in vitro and in cells.

The effect of apigenin and quercetin on CD38 activity in vitro was studied using the soluble ectodomain of human CD38 (17). We found that apigenin (Fig. 3A) inhibits in vitro CD38 activity with a half-maximal inhibitory concentration (IC₅₀) of 10.3 ± 2.4 μmol/L for the NAD⁺ase activity and an IC₅₀ of 12.8 ± 1.6 μmol/L for the ADP-ribosyl-cyclase activity (Fig. 3B and C). In vitro, quercetin (Fig. 3D) inhibits CD38 NAD⁺ase activity with an IC₅₀ of 10.3 ± 2.4 μmol/L. Apigenin and quercetin were used in the 0.5–100 μmol/L concentration range. Each measurement was done by triplicate. Data points were fitted to a standard competitive inhibition curve using a nonlinear regression program (GraphPad Prism) to yield the IC₅₀ value.

---

**FIG. 3.** The flavonoids apigenin and quercetin inhibit CD38 activity in vitro. A: Chemical structure of apigenin. B and C: In vitro NAD⁺ase (B) and ADP-ribosyl-cyclase (C) activity using human recombinant-purified CD38 and different concentrations of apigenin. D: Chemical structure of quercetin. E and F: In vitro CD38 NAD⁺ase activity (E) and ADP-ribosyl-cyclase activity (F) using human recombinant-purified CD38 and different concentrations of apigenin. In all the measurements, compounds were used in the 0.5–100 μmol/L concentration range. Each measurement was done by triplicate. Data points were fitted to a standard competitive inhibition curve using a nonlinear regression program (GraphPad Prism) to yield the IC₅₀ value.
13.8 ± 2.1 μmol/L (Fig. 3E) and ADP-ribosyl-cyclase activity with an IC50 of 15.6 ± 3.5 μmol/L (Fig. 3F).

**CD38 inhibition by quercetin and apigenin increases NAD⁺ levels in cells.** Although several flavonoids can inhibit purified recombinant CD38 in vitro (19), it is not known what effects these compounds have in cells. First, we measured the effect of quercetin on endogenous cellular CD38 activity. Inhibition of CD38 activity by quercetin in cells (IC50 = 16.4 ± 1.8 μmol/L) resembles the effect on the recombinant protein (Fig. 4A). Furthermore, we found that quercetin promotes an increase in intracellular NAD⁺ in a dose-dependent manner (Fig. 4B). To further confirm this effect, we incubated cells in PBS and measured intracellular NAD⁺ levels over time. We found that in untreated cells, NAD⁺ levels decrease with time (Fig. 4C), probably as a result of the removal of NAD⁺ precursors from the culture media. However, when the cells were treated with quercetin, NAD⁺ levels were stable over time, suggesting that inhibition of CD38 is enough to maintain intracellular NAD⁺ levels in the absence of NAD⁺ precursors. Finally, in order to confirm that the effect of quercetin on cellular NAD⁺ levels was dependent on CD38, we measured NAD⁺ after incubation with quercetin in wild-type and CD38 knockout MEFs. We found that quercetin promotes an increase in NAD⁺ in the wild-type MEFs but does not further increase NAD⁺ levels in CD38 knockout MEFs (Fig. 4D), indicating that the effect of quercetin on NAD⁺ levels is CD38 dependent.

Apigenin also inhibits CD38 activity in cells (Fig. 5A). In fact, inhibition of cellular CD38 was very similar to that observed with the purified recombinant protein (IC50 = 14.8 ± 2.2 μmol/L in cells and 10.3 ± 2.4 μmol/L in vitro). Apigenin treatment increased NAD⁺ levels in cells in a dose-dependent manner (Fig. 5B) and protected against NAD⁺ depletion when cells were incubated in PBS (Fig. 5C). Furthermore, treatment of CD38 knockout MEFs with apigenin had no effect on NAD⁺ levels (Fig. 5D), indicating that the effect of apigenin on NAD⁺ levels is mediated by CD38. Interestingly, we found that treatment of wild-type MEFs with apigenin decreased acetylation of RelA/p65 (Fig. 5E). However, in the CD38 knockout MEFs, RelA/p65 acetylation levels were undetectable in the control, and therefore we could not determine the effect of apigenin (Fig. 5E). These results are consistent with the effect of apigenin in intracellular NAD⁺ levels in these cells (Fig. 5D). Quercetin has been shown to activate SIRT1 in vitro (30), suggesting that it may activate SIRT1 activity by two different mechanisms. To rule out a possible direct effect of apigenin on SIRT1 activity, we measured in vitro recombinant SIRT1 activity in the presence of different concentrations of apigenin. We observed that apigenin does not activate SIRT1 directly (Fig. 5F). Combined, these results clearly demonstrate that apigenin inhibits CD38 in cells and by doing so promotes an increase in NAD⁺ levels that stimulates NAD⁺-dependent deacetylases.
CD38 inhibition by apigenin increases NAD$^+$ and decreases protein acetylation in mice. Apigenin and quercetin have been shown to ameliorate atherosclerosis in mice (25) and to protect against lipid accumulation in cells (25). However, the mechanism of action has not been elucidated. In fact, while most flavonoids activate AMPK, which could explain some of the metabolic effects observed, apigenin is a very poor AMPK activator (25).

Based on the results obtained in cells, we tested whether apigenin inhibits CD38 in vivo using a model of high-fat diet–induced obesity (5,15). We fed adult mice a high-fat diet for 4 weeks. After, we divided the mice randomly in two groups. Each group was injected daily with apigenin (100 mg/kg) or vehicle (DMSO) for a week. We found that mice that had been injected with apigenin had decreased CD38 activity in the liver (Fig. 6A), which correlated with an increase in hepatic NAD$^+$ levels compared with control mice (Fig. 6B). We then examined whether the apigenin treatment had an effect on the level of expression of several proteins involved in NAD$^+$ metabolism. As shown in Fig. 6C, we found no significant differences in the expression of CD38, SIRT1, or Nampt, the primary regulator of the NAD$^+$ salvage pathway. Furthermore, we did not see any changes in phosphorylation or total levels of AMPK (Fig. 6C). However, when we analyzed the liver samples using an acetyl-lysine antibody, we found that the apigenin treatment resulted in a statistically significant decrease in global acetylation of proteins (Fig. 6D and E).

To determine the relevance of SIRT1 in the deacetylation of proteins triggered by apigenin treatment, we used human HepG2 cells: a well-accepted cellular model for studying hepatic cellular signaling (15,25,31). We found that treatment with apigenin decreases total protein acetylation—an effect that is lost in the presence of the sirtuin inhibitor EX527 (Fig. 6F). Furthermore, treatment of HepG2 cells with apigenin decreased acetylation of p53 at K382 and also of RelA/p65 at K310: sites that are deacetylated by SIRT1 (Supplementary Fig. 1). Taken together, these results show that apigenin inhibits CD38 in vivo and is associated with increased NAD$^+$ and decreased protein acetylation, likely through the activation of SIRT1.

CD38 inhibition by apigenin improves glucose homeostasis in vivo and promotes fatty acid oxidation in the liver. Finally, we tested whether apigenin protects against high-fat diet–induced hyperglycemia. We found that after 4 days of treatment, the mice treated with apigenin had significantly lower blood glucose levels compared with the control mice (Fig. 7A). Fasting blood glucose levels were also significantly lower after 1 week of treatment with apigenin (Fig. 7B). Moreover, we found that 1 week of treatment with apigenin was enough to improve glucose homeostasis in the mice (Fig. 7C and D). SIRT1 activation promotes fatty acid oxidation in the liver by inducing the expression of several
enzymes involved in fatty acid and cholesterol metabolism (32). In fact, SIRT1 activation in the liver prevents liver steatosis (5,14,15). Mice treated with apigenin had increased expression of the enzymes MCAD and LCAD in the liver (Fig. 8A), suggesting that apigenin treatment enhanced fatty acid oxidation. We confirmed these data by measuring total triglyceride content in the liver. Indeed, we found that the mice treated with apigenin had lower triglyceride levels in the liver compared with control mice (Fig. 8B), showing that apigenin promotes hepatic lipid oxidation. To further confirm this finding, we measured lipid accumulation in cells, using an in vitro model of hepatic steatosis (15). We found that apigenin decreases lipid accumulation in cells and that this effect was completely blocked by the SIRT1 inhibitor EX527 (Fig. 8C). Together, these results show that inhibition of CD38 by apigenin, and perhaps by other flavonoids, constitutes a pharmacological approach to activate sirtuins and treat high-fat diet-induced metabolic disorders. Furthermore, our results point to CD38 as a novel pharmacological target to treat metabolic diseases.

DISCUSSION

The alarming expansion of metabolic diseases has triggered a considerable effort in the development of pharmacological strategies to prevent and treat them. In this regard, the study of sirtuins and specifically SIRT1 has become of great relevance due to the many beneficial effects of their action (8,9). In fact, how to achieve SIRT1 activation in vivo is a subject of intense investigation. One of the strategies to achieve such activation has been the use of drugs that directly target SIRT1. Resveratrol (16) and SRT1720 (33) are two of the early SIRT1-activating compounds that improve metabolism and protect against metabolic disorders, although there is a debate about their mechanism of action (34–36). Another mechanism to achieve SIRT1 activation in vivo is to raise intracellular levels of NAD+ either by increased synthesis or diminished degradation (5–7,18). Previously, we have shown that the enzyme CD38 is the principal regulator of intracellular NAD+ levels in mammalian tissues (17). In fact, we were the first to show that increasing NAD+ levels by deletion of
CD38 protects against diet-induced obesity through SIRT1 activation (5). Other research groups later confirmed the importance of NAD⁺ in the prevention of metabolic diseases. Yoshino et al. (7) showed that administration of nicotinamide mononucleotide (a NAD⁺ precursor) to mice protects against high-fat diet–induced metabolic disorders. Bai et al. (6) obtained similar results using PARP1 knockout mice. Taken together, the evidence shows that pharmacological interventions that increase NAD⁺ are a promising avenue for treating metabolic disorders. However, the mechanism by which cellular NAD⁺ is increased may have different long-term outcomes. We followed survival of wild-type, CD38 knockout, and PARP1 knockout mice fed a high-fat diet. Preliminary studies with small numbers of mice suggest that CD38 knockout mice have increased average and maximum life span compared with wild-type mice when they are fed a high-fat diet. However, in the PARP1 knockout mice, which also have increased cellular NAD⁺ levels (6), the outcome was opposite to this (Supplementary Fig. 2), with the PARP1 knockout mice having a decreased life span compared with the wild-type mice. This difference in survival could be explained by the fact that PARP1 is involved in genomic stability (37) and DNA repair both in the nucleus (37) and in mitochondria (38,39). This suggests that although CD38 and PARP1 knockout mice have similar protection against metabolic disorders, they may have distinct effects on longevity.

Here, we describe for the first time that the flavonoid apigenin is a CD38 inhibitor, and both apigenin and quercetin promote changes in intracellular NAD⁺ levels. This increase in NAD⁺ levels leads to changes in protein acetylation likely due to an increase in sirtuin activity. Furthermore, we show that apigenin improves glucose homeostasis and reduces lipid content in the liver in a model of high-fat diet–induced obesity. Our results suggest that lipid oxidation is increased by a SIRT1-dependent mechanism. However, it could also happen that fatty acid synthesis or export is altered, since SIRT1 has been shown to regulate both processes (40,41). Our results demonstrate that CD38 is a promising pharmacological target to promote sirtuin actions and to treat metabolic diseases.

Flavonoids, including apigenin and quercetin, have broad beneficial effects (20). These two flavonoids ameliorate atherosclerosis in mouse genetic models (25). Although some of the beneficial effects of flavonoids on metabolism are believed to be AMPK mediated (25), this has not been clearly elucidated. Indeed, apigenin is a very weak AMPK activator in vivo (25), which suggests an additional mechanism of action. Our findings provide mechanistic evidence that flavonoids can promote an increase in NAD⁺ levels through inhibition of CD38, resulting in changes in protein acetylation, most likely through stimulation of SIRT1 (Fig. 8D). Although we show here that CD38 inhibition affects SIRT1 activity, it is likely that other sirtuins will also be stimulated by CD38 inhibition. Interestingly, CD38 is also present and active in the mitochondria (42,43), where it may regulate mitochondrial NAD⁺ levels and mitochondrial sirtuin activity.

It is likely that, similar to what happens with many other natural compounds, apigenin and quercetin have other cellular targets besides CD38. However, we clearly show that the increase in cellular NAD⁺ levels promoted by these compounds depends on CD38. More importantly, our findings support the idea that pharmacological inhibition of CD38 can be achieved as a strategy to treat obesity and obesity-related diseases. Further research will help to develop highly selective CD38 inhibitors that may be used as an approach to treat metabolic syndrome in humans.

N.L.P. performed the library screening, performed qPCR, designed experiments, discussed and analyzed data, and corrected the manuscript. V.C. measured CD38 activity and evaluated the effect of CD38 and CD38 inhibitors on protein acetylation. A.P.G. performed qPCR. M.T.B. performed the longevity studies. L.O. analyzed tissue samples. T.A.W. measured CD38 activity. D.A.S. and E.N.C. developed the original idea, designed experiments, discussed and analyzed data, and corrected the manuscript. E.N.C. is the guarantor of this work and, as such, had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

The authors thank Caroline Shamu and the staff at Harvard’s Institute of Chemistry and Cell Biology facility, where the small-molecule screen was conducted.
