Received 15 December 2009/Accepted 9 May 2010

Biologically active, passive treatment systems are commonly employed for removing high concentrations of dissolved Mn(II) from coal mine drainage (CMD). Studies of microbial communities contributing to Mn attenuation through the oxidation of Mn(II) to sparingly soluble Mn(III/IV) oxide minerals, however, have been sparse to date. This study reveals a diverse community of Mn(II)-oxidizing fungi and bacteria existing in several CMD treatment systems.

Acidic, metal-laden mine drainage is a significant problem for many regions in the United States and throughout the world. In Appalachia, centuries of coal mining has left thousands of abandoned mines that are discharging waters containing elevated levels of metals—particularly Mn, with concentrations as high as 150 mg liter−1 (see reference 9 and references therein and reference 23). In the eastern United States, one of the most common methods to remediate coal mine drainage (CMD) is the use of biologically active limestone treatment beds. In essence, dissolved metals, such as Mn(II), are immobilized in the treatment bed via precipitation of sparingly soluble oxide minerals (23, 24) that effectively remove other metal contaminants (e.g., Ni, Co, and Zn) through coprecipitation and surface adsorption reactions (26, 31, 47).

The importance of microbial activity in the remediation of Mn-contaminated waters has frequently been observed (6, 20, 21, 24, 25). Several strains of Mn(II)-oxidizing bacteria have even been used for treating manganiferous mine waters (49). Recently Mariner et al. (32) identified Mn(II)-oxidizing fungi, in addition to bacteria, successfully growing in a Mn-attenuating bioreactor for treatment of mine waters. We also observed that the addition of fungicides inhibited Mn(II) oxidation in laboratory-based CMD treatment simulations (W. D. Burgos, H. Tan, C. M. Santelli, and C. M. Hansel, presented at the National Meeting of the American Society of Mining and Reclamation, Pittsburgh, PA, 5 to 11 June 2010), suggesting a role for fungal activity in Mn remediation. The identities, growth characteristics, and oxidation mechanisms of the microbial community contributing to CMD remediation, however, remain largely unresolved. The objective of this study was to define the Mn(II)-oxidizing microbial community existing in passive treatment systems designed to remove dissolved Mn(II) from CMD. Because the mechanisms of microbial Mn(II) oxidation are not fully elucidated and are not genetically tractable (13, 18), we initiated an extensive culture survey to identify microorganisms that catalyze Mn(II) oxidation and precipitate Mn(III/IV) oxide minerals. These results provide the foundation for future explorations identifying the key players in CMD remediation and factors impacting their activity.

In October 2007, we sampled four Mn attenuation beds—Saxman Run (SRC1) and DeSale phases I, II, and III (DS1 to DS3)—in central Pennsylvania that are currently treating exceptionally high Mn concentrations (up to 119 mg liter−1; 2.2 mM) generated from abandoned coal mines. Each system has a slightly different design (for a further description, see reference 21) and treatment load; however, all systems have wetlands and limestone-filled beds (to raise pH) in series. At the time of sampling, waters flowing into SRC1 had a near-neutral pH (6.6) and dissolved Mn was 28 mg liter−1 (500 μM). SRC1 was highly effective in removing dissolved Mn where the effluent had <0.05 mg liter−1 Mn (data courtesy of the Pennsylvania Department of Environmental Protection). Systems DS1 to DS3 treat waters with a pH range of 5.7 to 6.3, containing 46 to 119 mg liter−1 (0.85 to 2.2 mM) Mn, and each attenuates about 50% of the total Mn load.

Culture enrichments were initiated using Mn oxide-coated limestone and debris from the treatment systems. Serial dilutions to 1/104 for each sample were plated on 7 types of agar-solidified media with 20 mM HEPES (pH 7) and 200 μM MnCl2: AY (34); K, M, and Leptothrix (46); J and J plus acetate (22); and medium 3 (11). Mn(II)-oxidizing microorganisms were transferred to fresh media until cultures were deemed axenic. Mn(III/IV) oxides were confirmed using the LBB colorimetric assay (28) and electron microscopy (not shown).

Fungal isolates were identified using a combination of phylogenetic analysis and morphological characterization (Table 1), and bacteria were identified through phylogenetic analysis.
The image contains a table and text discussing the isolation and characterization of Mn(II)-oxidizing fungi and bacteria from CMD passive treatment systems. The table lists various species, their representative isolates, morphological descriptions, and growth rates, along with Mn²⁺ tolerance and growth rates for bacteria.

For morphological characterizations, fungi were grown on AY, potato dextrose agar, and malt extract agar for up to 12 weeks to induce sporulation. Isolates producing conidiogenous structures were examined using light microscopy to confirm species-level identification. For morphological characterizations, fungi were grown on AY, potato dextrose agar, and malt extract agar for up to 12 weeks to induce sporulation. Isolates producing conidiogenous structures were examined using light microscopy to confirm species-level identification. Growth rates for fungi (mm/day) were determined by measuring the increase in diameter with time. Growth rates for bacteria (OD 600/h) were determined by measuring the optical density at 600 nm (OD 600) with 200 μM ascorbic acid to dissolve Mn(III/IV) oxides. Rates were determined during exponential growth phase.

*Note: a = no isolates obtained.*

*Note: b = Growth rates for fungi (mm/day) were determined by measuring the increase in diameter with time. Growth rates for bacteria (OD 600/h) were determined by measuring the optical density at 600 nm (OD 600) with 200 μM ascorbic acid to dissolve Mn(III/IV) oxides. Rates were determined during exponential growth phase.*
other known Mn(II)-oxidizing species, suggesting that some Mn(II)-oxidizing species have a cosmopolitan distribution. *Microdochium bolleyi* and *Acremonium strictum* sequences are very similar (Fig. 1a) to those of Mn(II)-oxidizing Xylariales sp. UB32-1 (98% similarity, 18S rRNA) and *Acremonium* sp. KR21-2 (100% similarity, ITS), respectively, isolated from a stream bed in Japan (33, 34).

All other Mn(II)-oxidizing fungal isolates are classified as...
Pleosporales (Dothideomycetes class), although neither phylogenetic analysis nor morphological characterization could confirm the identification of several of these beyond the genus level. Two of these isolates do not have sequences with similarity to those of known Mn(II)-oxidizing species: DS3sAY3a, a *Pyrenochaeta* sp., and SRC1lrK21, identified as *Alternaria alternata* (Table 1 and Fig. 1a; see also Fig. S4a and S4b in the supplemental material). Conversely, most of these species are related to other known Mn(II)-oxidizing strains. For example, isolate SRC1lrM3a, a *Stagonospora* sp. (Table 1; see also Fig. S2b), is related to different Mn-oxidizing strains (Fig. 1a, 99% similarity); *Pleosporales* sp. IRB20-1 (33), isolated from a Japanese stream bed, and *Pleosporales* sp. RMF2, isolated from a prototype bioreactor treating Mn-contaminated mine waste in Wales, United Kingdom (32). Likewise, isolate DS1wsM30b, a *Phoma* sp. (Table 1; see also Fig. S3a), has high sequence similarity (≥98%, 18S) with *Phoma* sp. KMF1 from the Mn bioreactor and *Phoma* sp. KY-1, isolated from stream sediment (42). *Pithomyces chartarum* isolate DS1bioJ1b (Table 1; see also Fig. S3b) is 99% similar to Mn(II)-oxidizing *Paraconiothyrium* sp. WL-2, isolated from an artificial wetland in Japan (42), and *Pleosporales* sp. UB32-2, isolated from a Japanese stream bed (33); however, ITS analysis shows only 88% similarity to *Paraconiothyrium* sp. WL-2 (the ITS sequence for UB32-2 is not publicly available).

Although relatively few Mn(II)-oxidizing bacteria were recovered from the treatment systems, these isolates present similar phylogenetic diversity: 9 bacterial isolates represent 4 taxa (Fig. 1b and Table 1) belonging to three different phyla: *Firmicutes, Bacteroidetes,* and *Proteobacteria* (Alpha- and Gammaproteobacteria). *Bacillus* spp., represented by isolate DS3sK3a, are the most commonly recovered bacteria (Table 1). It is not surprising to recover *Bacillus* species from the treatment systems, because they are the most commonly isolated Mn(II)-oxidizing bacteria (12, 16) for marine systems as well. Isolate DS3sK1h, a *Pseudomonas* sp., is similarly related to other previously identified Mn(II)-oxidizing bacteria, such as *P. putida* strain MnB1 and *Pseudomonas* sp. LOB-2, isolated from the deep ocean (≥97% sequence similarity; Fig. 1b) (46).

Two previously unreported Mn(II)-oxidizing bacterial species were also recovered: *Agrobacterium* sp. (isolate SRC1K21b), an alphaproteobacterium, and *Flavobacterium* sp. (isolate DS2psK4b), a member of the *Bacteroidetes* (Table 1 and Fig. 1b). The isolation of a *Flavobacterium* sp. further expands the taxonomic representation of Mn oxidizers—to our knowledge, members of the *Bacteroidetes* have never been demonstrated to oxidize Mn(II). *Alphaproteobacteria*, on the other hand, account for a large portion of cultured Mn(II)- oxidizing bacterial representatives (3, 15, 22, 44, 46) and other metal-oxidizing bacteria (39).

Microbial communities living in CMD treatment systems are exposed to widely fluctuating environmental conditions and metal concentrations; therefore, the ability to tolerate and grow in various Mn concentrations was tested for all isolates. Fungi and bacteria were grown in media supplemented with Mn^2+ at the following concentrations: 0, 0.5, 1, 5, and 10 mM MnCl_2. Our results show that all isolates, with the exception of *Microdochium bolleyi* and *Pithomyces chartarum*, grew and oxidized Mn(II) at Mn concentrations greater than those observed in the treatment systems (Table 1). Metal tolerance of bacterial strains was somewhat unexpected since it is generally believed that fungi are more tolerant than bacteria to high concentrations of heavy metals, often leading to a prevalence of fungi in metal-contaminated soils (7, 8, 27, 37). It is possible that these bacterial strains have developed metal tolerance in the treatment systems; the development of Mn tolerance has been observed previously (1) in the Mn(II)-oxidizing bacterium *Leptothrix discophora*.

Mn(II) exposure experiments also show that growth rates (Table 1) remain constant with various metal concentrations for many of the isolates (e.g., *Microdochium bolleyi* and *Bacillus* sp., even at 10 mM Mn concentrations (data not shown). Some species, however, grow fastest at lower Mn(II) concentrations (e.g., *Stibella aciculosa*), whereas others had increased growth rates at high Mn concentrations that were even more pronounced at 10 mM Mn (e.g., *Stagonospora* sp., 3.5 mm/day). Decreased (5) or similar (34, 41) growth rates at higher dissolved Mn(II) concentrations have previously been observed for many nonoxidizing and Mn-oxidizing ascomycota and bacteria (14, 22), suggesting a possible toxic effect of high metal concentrations. Faster growth at very high Mn(II) concentrations, however, is somewhat surprising, although small concentrations have stimulated growth of some Mn-oxidizing bacteria relative to metal-free conditions (14, 15). Since fungi and all known Mn(II)-oxidizing bacteria are heterotrophs and therefore do not gain energy from the oxidation reaction, these organisms may be benefiting from either the presence of Mn oxide minerals (e.g., scavenging of nutrients, immobilization of metals, or UV protection) or potentially an increased uptake of dissolved Mn(II) for cellular functions or scavenging of reactive oxygen species (see references 43 and references therein).

Here we introduce new bacterial and fungal players in the oxidation of Mn(II). We also reveal a diversity and predominance of fungi within cultivable Mn(II)-oxidizing communities in CMD passive treatment systems. It is not entirely unexpected to obtain fungi in such environments, since fungi often possess multiple mechanisms to tolerate environmental stresses (e.g., nutrient fluctuations, desiccation, or high metal loading). Consequently, it is becoming increasingly evident that fungi represent great (and often overlooked) potential for the remediation of a wide range of pollutants, including metals (for examples, see references 17 and 48). The results in this and previous studies (32; Burgos et al., presented at the National Meeting of the American Society of Mining and Reclamation, 2010) suggest fungi also contribute to the remediation of Mn-contaminated mine drainage, warranting continued investigations of the cultivated Mn(II)-oxidizing fungi. Future investigations of these organisms revealing the mechanisms of Mn(II) oxidation and the factors influencing optimal growth and activity will greatly aid the engineering of efficient systems for CMD bioremediation and likely beyond.

**Nucleotide sequence accession numbers.** Sequences were submitted to the GenBank database with the following accession numbers: 16S rRNA genes, HM216202 to HM216205; 18S rRNA genes, HM216184 to HM216192; 28S rRNA genes, HM216193 to HM216201; and ITS region, HM216206 to HM216214.
