Axon growth is essential for the establishment of a functional nervous system as well as for the restoration of neuronal connectivity after injury or disease. It has long been hypothesized that re-activation of developmental growth mechanisms might help to achieve axon regeneration in the injured adult nervous system (Filbin, 2006). The role of MAP kinases in axon growth signaling has been much studied and discussed (Markus et al., 2002; Hanz and Fainzilber, 2006; Agthong et al., 2009; Hollis et al., 2009). However, depending on the model systems used, the outcomes have been controversial or even contradictory (Pernet et al., 2005; Sapieha et al., 2006; Hollis et al., 2009). We have shown that RAF–MEK signaling robustly promotes axon growth in primary sensory neurons in vitro (Markus et al., 2002). In vivo, conditional gene targeting studies have shown that RAF signaling is necessary for developing sensory neurons to arborize in their target fields in the skin (Zhong et al., 2007). However, it remains unknown whether RAF signaling is sufficient to enable axon growth in vivo or whether concomitant activation of other signaling pathways is necessary to drive long-range axon projections. Furthermore, it is unclear whether this pathway can promote axon growth in neuronal populations beyond the sensory neurons and the extent to which it can be harnessed to promote regeneration in the injured central nervous system (CNS). To address these questions, we have used conditional B-RAF gain-of-function mouse models to show that cell-intrinsic RAF signaling is a crucial pathway promoting developmental and regenerative axon growth in the peripheral and central nervous systems.

Activation of intrinsic growth programs that promote developmental axon growth may also facilitate axon regeneration in injured adult neurons. Here, we demonstrate that conditional activation of B-RAF kinase alone in mouse embryonic neurons is sufficient to drive the growth of long-range peripheral sensory axon projections in vivo in the absence of upstream neurotrophin signaling. We further show that activated B-RAF signaling enables robust regenerative growth of sensory axons into the spinal cord after a dorsal root crush as well as substantial axon regrowth in the crush-lesioned optic nerve. Finally, the combination of B-RAF gain-of-function and PTEN loss-of-function promotes optic nerve axon extension beyond what would be predicted for a simple additive effect. We conclude that cell-intrinsic RAF signaling is a crucial pathway promoting developmental and regenerative axon growth in the peripheral and central nervous systems.
activation of intraneuronal RAF–MEK signaling is sufficient to promote robust axon growth in developing and regenerating neurons in the peripheral nervous system and CNS.

RESULTS
Activation of B-RAF signaling alone is sufficient to promote sensory axon extension during early development
In vivo, the neurotrophin nerve growth factor (NGF) signals through its receptor kinase TrkA to promote developmental extension of dorsal root ganglion (DRG) nociceptive TrkA+ peripheral axons into the epidermis. To examine whether RAF signaling alone is sufficient to promote long-range axon extension of TrkA-positive neurons, we set out to selectively activate RAF kinase signaling in these neurons in a TrkA-null background.

To this end, we first conditionally activated RAF signaling in a WT background using a genetically modified loxP-STOP-loxP-Braf<sup>V600E</sup>(LSL-kaBraf) knock-in mouse line (Mercer et al., 2005), in which a kinase-activated B-RAF (kaB-RAF) mutant is expressed from the endogenous B-RAF locus upon Cre recombination. We next bred LSL-kaBraf mice with a neuronal

Figure 1. Conditional expression of kaB-RAF specifically activates MAP kinase signaling in the nervous system. (A) E18.5 mouse embryos expressing kaB-RAF develop grossly normally, except for substantial hydrocephalus. (B) DRG size is unaffected by kaB-RAF expression. nestin promoter–driven Cre deleter (nes-Cre; Tronche et al., 1999). In DRG neurons, nes-Cre–mediated recombination occurs as early as embryonic day (E) 11.5 (Galabova-Kovacs et al., 2008). Embryos heterozygously expressing kaB-RAF progressively developed macrocephaly from E13.5 onwards (Fig. 1 A) but appeared otherwise normal, including normally sized DRGs (Fig. 1 B). The known RAF effectors were activated in neuronal tissues expressing Cre recombinase, as indicated by elevated phospho-MEK1/2 (pMEK1/2) and pERK1/2 in the neocortex and spinal cord of E12.5 LSL-kaBraf:nes-Cre mice (Fig. 1, C and D). Note that compared with MEK1/2, ERK1/2 activation appears minor in the kaB-RAF–expressing DRGs; this is because of relatively high levels of pERK1/2 in the DRG at baseline. B-RAF activation did not affect mTOR phosphorylation (Fig. 1 E). Levels of pAKT, pS6K, and pGSK3β were not changed significantly in the DRG of LSL-kaBraf:nes-Cre mice (Fig. 1 F), indicating minimal cross talk between the MAP kinase and PI3-kinase–AKT pathways. Because the expression of kaB-RAF is under the control of endogenous Braf promoter, the expression level of B-RAF protein is not changed in
the DRG and spinal cord at E12.5 (Fig. 1 G). At E13.5, the branching pattern of sensory nerves in the skin was not changed by kaB-RAF expression (Fig. 1, H and I).

**B-RAF activation rescues nociceptor axon extension in embryos lacking TrkA**

To test whether kaB-RAF is sufficient to drive nociceptor axon growth in the absence of TrkA signaling, we next mated the LSL-kaBraf:nes-Cre line with available TrkA taulacZ and Bax−/− lines to generate LSL-kaBraf:TrkA taulacZ/taulacZ:Bax−/−:nes-Cre mice. In TrkA taulacZ mice, the WT TrkA gene is replaced by a taulacZ expression cassette, such that the axonal morphology of putative TrkA+ neurons can be visualized by β-gal staining (Moqrich et al., 2004). Because TrkA expression is absent in homozygous TrkA taulacZ/taulacZ mice, we refer to the “TrkA taulacZ/taulacZ” as “TrkA−/−” in the text below. Removal of the Bax gene blocks apoptosis in embryonic DRG neurons, rescuing them from cell death that is otherwise observed in the absence of TrkA signaling. The Bax−/− background thus allows for the molecular dissection of signaling pathways that specifically affect axon growth (Knudson et al., 1995; Lentz et al., 1999; Patel et al., 2000; Markus et al., 2002; Kuruvilla et al., 2004; Moqrich et al., 2004). In TrkA−/−:Bax−/− mice, DRG neurons survive, but sensory afferent innervation in the skin is completely abolished (Fig. 2, A and B, middle; Patel et al., 2000). Compared with control littermates (which include LSL-kaBraf:TrkA−/−:Bax−/−, nes-Cre:TrkA−/−:Bax−/−, and TrkA−/−:Bax−/− genotypes), in which we detected no LacZ-positive fibers in the skin at E16.5, expression of kaB-RAF in the TrkA−/− background, in which we detected no LacZ-positive fibers in the skin at E16.5, expression of kaB-RAF partially restored cutaneous sensory axon projections (Fig. 2, A–C). The morphologies of the radial thoracic trajectories derived from spinal DRGs as well as those growing from trigeminal ganglia induced by kaB-RAF in the TrkA−/− background were grossly similar to those seen in control mice. 

**Epidermal innervation of the footpad was partially rescued by kaB-RAF (Fig. 3, A and B). Thus, sustained B-RAF kinase activity can, to a large extent, substitute for TrkA-mediated axon growth signaling in presumptive TrkA+ sensory neurons.**

**B-RAF–mediated axon growth indirectly rescues calcitonin gene-related peptide (CGRP) expression in TrkA−/−:Bax−/− neurons**

CGRP expression in the peptidergic subset of nociceptive DRG neurons is induced by skin-derived factors and therefore indicates that sensory axon peripheral innervation into the skin is complete (Hall et al., 1997, 2001; Patel et al., 2000; Xu and Hall, 2007). In TrkA−/−:Bax−/− mice, DRG neurons and their centrally projecting axons are devoid of CGRP because of the lack of cutaneous innervation as previously described (Patel et al., 2000), whereas CGRP expression in the spinal motor neurons remains unaffected (Fig. 4 A, middle).
B-RAF gain–of–function restored CGRP expression in the absence of TrkA (Fig. 4 A, right). Note also that in contrast to the projections in the periphery, the growth of presumptive TrkA–positive afferent projections in the dorsal horn is independent of TrkA signaling (Fig. 4 B, middle; Patel et al., 2000; Harrison et al., 2004) and that kaB-RAF expression caused overgrowth of these afferents (Fig. 4 B, right) but not of peripheral projections (Fig. 1). In vitro, kaB-RAF alone did not induce CGRP expression in DRG neurons (Fig. 4 C, top); this required the addition of NGF and skin-conditioned medium as previously reported (Fig. 4 C, bottom; Hall et al., 1997; Patel et al., 2000; Xu and Hall, 2007). In addition, we have shown previously that loss of both B- and C-RAF in DRGs does not abrogate the CGRP expression (Zhong et al., 2007). These data together indicate that the restoration of CGRP expression in LSL-kaBraf:nes-Cre::TrkA−/−:Bax−/− DRG neurons is not directly caused by the elevation of neuron-intrinsic B-RAF activity, but indirectly through the restoration of cutaneous innervation and subsequent retrograde signaling from skin–derived factors.

**kaB-RAF causes overgrowth of nociceptive and proprioceptive afferent fibers in the spinal cord**

In WT mice, different subpopulations of sensory neurons project from the DRG to highly specific targets in the spinal cord. Specifically, nociceptive TrkA+ fibers terminate in the superficial laminae I and II of the dorsal horn, and proprioceptive parvalbumin–positive afferents project to intermediate laminae or to the ventral spinal cord.

In B-RAF gain–of–function mice, we observed excessive growth of both nociceptive and proprioceptive afferents (Fig. 5). Nociceptive axons normally restricted to superficial dorsal horn extended ectopically into deeper layers of dorsal spinal cord, and many axons aberrantly crossed the midline (Fig. 5 A). This kaB-RAF–driven overgrowth was substantially rescued by concomitant elimination of MEK1/2, the canonical downstream kinases of RAF (Fig. 5 C), suggesting that the effect of kaB-RAF expressed from the endogenous Braf locus depends strictly on canonical signaling.

In WT mice, the central proprioceptive afferents enter the cord medially at tightly circumscribed dorsal root entry zones (DREZs; Fig. 5 B, left). kaB-RAF expression caused the proprioceptive sensory axons to enter the spinal cord all across its surface and to aberrantly terminate some branches in the superficial dorsal laminae (Fig. 5 B, right). Proprioceptive axons in the DREZs normally are subject to repulsive guidance from Semaphorin 6C/D (Sema6) expressed in the spinal cord, acting on PlexinA1 on the sensory axons (Yoshida et al., 2006). kaB-RAF expression did not detectably alter the protein (Fig. 5 D) or transcript levels (RNASeq; not depicted).
of these factors in E12.5 DRG and spinal cord. The overgrowth phenotype for both nociceptive and proprioceptive afferents was observed at all levels of the spinal cord (Fig. 5, E–J). This phenotype suggested that reactivation of the B-RAF pathway in injured adult neurons might be exploited to promote regeneration.
Figure 6. Activation of B-RAF signaling in mature DRG neurons elevates their growth competency. **kaB-RAF enables regeneration of injured adult DRG central axons across the DREZ**

To test whether activation of B-RAF kinase signaling can promote axon regeneration of injured mature CNS neurons, we used an optic nerve regeneration model (Fig. 8, A and B; Park et al., 2008; Benowitz and Yin, 2010). 8–12-wk-old *LSL-kaBraf*: *Bax<sup>−/−</sup>* mice and *Bax<sup>−/−</sup>* littermates (Fig. 8 C), consistent with previous observations that survival alone is not sufficient to promote growth of adult RGC axons (Goldberg et al., 2002).

Combined deletion of the canonical RAF effector kinases MEK1 and MEK2 substantially suppressed the regenerative axon growth caused by *kaB-RAF* (Fig. 8 E), indicating that *kaB-RAF* drives axon growth through the canonical MEK effectors. Whereas the length of axon extension induced by

B-RAF gain-of-function is comparable with the maximal axon growth reported in PTEN deletion mice (Fig. 8F; Park et al., 2008), in a direct comparison, we found up to a 3.9-fold higher density of regenerating axons in the LSL-kaBraf:Bax<sup>-/-</sup> mice 1.5 mm distal to the crush site than is seen in the crushed Pten<sup>−/-</sup>:Bax<sup>-/-</sup> optic nerve (Fig. 8D, F, and G).
DISCUSSION

An understanding of the mechanisms that drive axon growth is important, both to decipher how connectivity develops in the nervous system and to develop therapeutic strategies for nervous system repair after injury or disease. We show that the RAF–MEK axis plays a key role in axon growth signaling. Activation of B-RAF in neurons is sufficient to drive sensory axon growth in the embryo, to enable adult sensory axons to regenerate across the DREZ and further into the spinal cord, and to induce robust regeneration of adult retinal axons in the injured optic nerve. Both developmental DRG axon overgrowth in the spinal cord and mature RGC axon regeneration in the optic nerve were abrogated by concomitant ablation of MEK1 and MEK2. We thus establish classical cell-autonomous RAF–MEK signaling as a fundamental driver of axon growth. We should note that this pathway seems to be selective to axon growth signaling because we have never observed that B-RAF activation supports neuronal survival (unpublished data).

In vitro work has long suggested a potential role for RAF–MEK signaling in axon growth. Previous in vivo data, however, have been scarce and controversial. In the retina, for example, pharmaceutical inhibition of MEK–ERK signaling abrogated optic nerve regeneration supported by FGF2 (Sapiha et al., 2006). Two putative intracellular activators of RAF signaling, BAG1 and Mst3b, have been shown to promote regenerative axon growth in the optic nerve (Planchamp et al., 2008; Lorber et al., 2009), but the expression of a constitutively active MEK1 did not drive any regeneration in the optic nerve (Pernet et al., 2009). Others have concluded that ERK activity promotes RGC axon regeneration via an indirect mechanism dependent on glial cells (Müller et al., 2009). Although it is likely that multiple mechanisms, direct as well as indirect, will contribute to axon regeneration in the inhibitory environment of the CNS, the current cacophonous state of the field is likely caused by the mainly indirect approaches of incomplete penetrance that have been taken by various laboratories. When using small molecule inhibitors or transient viral overexpression of interfering or activating constructs, it is difficult to accurately titrate the dose for the entire duration of an experiment. We believe that we have applied a stringent approach toward activation of RAF signaling in RGCs, and our data argue strongly for a direct positive effect of RAF–MEK signaling on axon growth and regeneration of RGCs, as well as in DRG neurons. Possible downstream mechanisms beyond the MEK kinases remain speculative at this point. Stabilization of microtubules improves axon regeneration in a spinal cord injury (SCI) model through both neuron-intrinsic and -extrinsic mechanisms (Hellal et al., 2011), and it is likely that activation of RAF–MEK signaling will directly affect microtubule stability in injured axons via its effects on microtubule-regulating enzymes such as HDAC6 (Williams et al., 2013). Furthermore, B-RAF has been shown to directly interact with tubulin (Bonfiglio et al., 2011). Activation of B-RAF signaling is also likely to trigger the expression of axon growth–enhancing gene sets in injured neurons. The elucidation of exact mechanisms awaits further study.

kaB-RAF expression and PTEN deletion synergize to increase axon regenerative growth

To test whether combined activation of the B-RAF and PI3-kinase–mTOR pathways can further boost axon growth capacity in injured adult retinal ganglion neurons, we performed the optic nerve regeneration experiments using double LSL-kaBraf;Pten−/− mice. Both the numbers and length of regenerating axons were increased in the optic nerve of the LSL-kaBraf;Pten−/− mice compared with those in single LSL-kaBraf or in Pten−/− mice (Fig. 9 A). The synergistic effect of activating both B-RAF and PI3-kinase signaling is most apparent at the longest lengths of axon regeneration (Fig. 9 B). Note that the mice in these experiments were from a Bax WT background to enable direct comparison with the original PTEN deletion data (Park et al., 2008); however, this means that possible survival-promoting effects of the mutant alleles cannot be excluded.
The developmental phenotypes we observed in the B-RAF gain-of-function embryos were generally complementary to those previously observed in B-RAF/C-RAF loss-of-function mice (Zhong et al., 2007). In contrast to nociceptors’ peripheral projections, the development of their central projections does not depend on NGF/TrkA signaling (Pate et al., 2000; Harrison et al., 2004; Zhong et al., 2007). Notably, we found that activation of B-RAF resulted in overgrowth of both proprioceptive and nociceptive axons in the spinal cord, whereas the expression of two known repulsive signaling molecules in the dorsal cord and DRG; Semaphorin and PlexinA1, remained unaltered. Thus, kaB-RAF appears to activate a normally quiescent axon growth signaling pathway in the central sensory axons that seems to be unaffected by repulsive guidance cues.

The importance of this effect, the lack of response to repulsive or inhibitory cues, becomes clear in the context of regeneration of central sensory branches after dorsal root crush injury. Sensory axons expressing kaB-RAF robustly regenerated into the DREZ and spinal cord.

The regeneration failure of DRG axons after dorsal root avulsion injuries has been variously attributed to the lack of intrinsic growth capacity, to extrinsic growth barriers such as glia-associated growth inhibitors at the DREZ, and to premature synaptic differentiation (Han et al., 2012; Smith et al., 2012). Application of neurotrophic factors acting via tyrosine kinase receptors has shown substantially enhanced regeneration (Ramer et al., 2000; Wang et al., 2008; Harvey et al., 2010), even functional recovery with the systemic administration of arterin (Wang et al., 2008), although these results await independent replication. Future studies will test whether a combination of RAF activation with trophic growth factors can further enhance axon regeneration and reinnervation of presumptive targets in the spinal cord.

Compared with spinal cord lesions, the optic nerve’s simple structure allows for clear evaluation of both lesion and regeneration. In recent years, the optic nerve model has revealed several intracellular signaling pathways that can drive CNS axon regeneration, most prominently the PI3-kinase–mTOR and the JAK–STAT pathways, engaged by growth factor tyrosine kinase receptors and cytokines (Park et al., 2008; Smith et al., 2009; Buchser et al., 2012; Leibinger et al., 2013; Pernet et al., 2013). Combined deletion of endogenous inhibitors of these two pathways enhanced regeneration above the level reported for deletion of either gene alone (Sun et al., 2011). Activation of PI3-kinase–mTOR via PTEN deletion also enhanced regenerative growth in an SCI model (Liu et al., 2010), suggesting that results obtained in the optic nerve crush model may generally translate to SCI models. Here, we show that the classic growth factor signaling module RAF–MEK enables axon regeneration in the optic nerve at least as powerfully as any previously reported single molecule manipulation and that the combination of kaB-RAF with activation of PI3-kinase–mTOR via PTEN deletion enhances optic nerve axon regeneration even more strongly than would be expected for a simple additive effect.
For CGRP expression assay, E12.5 DRGs derived from Surgeons and all other personnel performing experi
ments and analyses were blinded as to genotypes. The crush-regeneration and Optic nerve crush.

Drugs were injected s.c. with tamoxifen (5 µg/10 g body weight) for a consecutive 5 d, followed by 5 d of rest. Unilateral sciatic nerve crush. Sciatic nerve crush was then performed as described previously (Zhong et al., 1999). Adult weight) for a consecutive 5 d, followed by 5 d of rest. Unilateral sciatic nerve crush.

Dorsal root crush. Surgeons and all other personnel performing experiments and analyses were blinded as to genotypes. 10-14-wk-old mice were injected s.c. with tamoxifen (5 µg/10 g body weight) for a consecutive 5 d, followed by 5 d of rest. Unilateral sciatic nerve crush was then performed as described previously (Zhong et al., 1999). Adult DRGs were collected and cultured as described previously (Zou et al., 2009). Images were taken using a Carl Zeiss LSM710/NLO confocal microscope. Axon length was quantified as described previously (Zou et al., 2009).

Optic nerve crush. Surgeons and all other personnel performing experiments and analyses were blinded as to genotypes. The crush-regeneration and axon counting protocol is adapted from Park et al. (2008). Whole-mount optic nerves were treated with FocusClear (CellExplorer Labs) and scanned using an LSM710/NLO multiphoton confocal microscope. OD was determined with the Carl Zeiss ZEN2009 software.

LacZ staining. E16.5 embryos were fixed in 4% paraformaldehyde and stained with X-gal using EMD Millipore’s Tissue Base staining solution according to the manufacturer’s protocol. After imaging of axon skin innervation, embryos were dehydrated using a methanol in PBS dilution series (25–50%, 75–95%, and 100%), followed by incubation in 50% methanol: 50% benzyl alcohol/benzyl benzoate (BABB), and subsequently cleared in 100% BABB (Sigma-Aldrich). Specimens were imaged with a M205A stereomicroscope equipped with a DFC310FX color digital camera system (Leica).

DRG culture. For CGRP expression assay, E12.5 DRGs derived from LSL-kdrafBac+/−;nes-Cre embryos were cultured with 100 ng/ml NGF (Alomone Labs) and skin-conditioned medium for 8 d. DRG neurons cultured in N2-supplied MEM (without NGF) were used as control. Both cultures where treated with FdU (5-fluoro-2-deoxyuridine; Sigma-Aldrich). Culture media were changed every 12 h. The cells were fixed 8 d thereafter, and the cells were stained for CGRP and TrkA. For axon growth and neuron survival assays, DRGs were dissected from E12.5 embryos with the desired genotypes as described previously (Markus et al., 2002; Zhong et al., 2007). The cells were dissociated and plated on laminin-coated coverslips. Cells were then cultured in serum-free media supplemented with 1× N2 (Invitrogen) and 1% BSA. FdU, NGF, or AAV2-Cre (Vector Laboratories) were added as described previously (Markus et al., 2002; Zhong et al., 2007).

Sciatic nerve crush. Mice were injected with tamoxifen (2 µg/10 g body weight) for a consecutive 5 d, followed by 5 d of rest. Unilateral sciatic nerve crush was then performed as described previously (Zhong et al., 1999). Adult DRGs were collected and cultured as described previously (Zou et al., 2009).

We would like to thank Louis Reichardt for the Trkα+/− mice and TRKA antibody, Catin A Pritchard for the LSL-kdrafBac mice, Eric Turner for the Brn3a promoter, and Thomas Jessell for the PlexinA1 antibody. Larry Benowitz provided experimental advice on the optic nerve injury model. Rajiv Ratan, David Ginty, William D. Snider, and Annette Markus are acknowledged for insightful discussion and suggestions.
