Dicke quantum spin glass of atoms and photons

(Dated: November 4, 2011)

Recent studies of strongly interacting atoms and photons in optical cavities have rekindled interest in the Dicke model of atomic qubits coupled to discrete photon cavity modes. We study the multimode Dicke model with variable atom-photon couplings. We argue that a quantum spin glass phase can appear, with a random linear combination of the cavity modes superradiant. We compute atomic and photon spectral response functions across this quantum phase transition, both of which should be accessible in experiments.

Introduction. Ultracold atoms in optical cavities have emerged as attractive new systems for studying strongly-interacting quantum many body systems. Photon exchange can mediate long-range interactions between the atomic degrees of freedom, and this opens up rich possibilities for correlated phases. In the celebrated atomic realizations of the superfluid-insulator quantum phase transition \([\Phi_0]\), the light field acts in a secular manner, creating a potential which traps the atoms in an optical lattice; consequently the atom-atom interactions are only on-site, and this limits the range of possible phases. In contrast, the seminal recent experiments of Baumann et al. \([2,3]\), realizing a supersolid phase, have long-range interactions mediated by active photon exchange \([4]\).

Baumann et al. argued that their experiments could be described by the Dicke model, as in the proposal of Nagy et al. \([5]\). The Dicke model couples photons in a single cavity mode uniformly to \(N\) atomic two-level systems (‘qubits’). In the limit \(N \to \infty\), this model exhibits a phase transition \([6-9]\) to a “superradiant” phase when the atom-photoncoupling is strong enough. In terms of the qubits, the superradiant phase is a ‘ferromagnet’ which spontaneously breaks a global Ising symmetry, and so we refer to it as FM\(_{SR}\). In the experiments by Baumann et al., the superradiance of the cavity photon mode is accompanied by ‘self-organization’ of the atoms into a density wave pattern \([10-12]\).

Here we study extensions of the Dicke model to multiple photon cavity modes, and with non-uniform couplings between the atomic qubits and the photon modes. Spatial mode variations for the single-mode Dicke model were described recently by Gopalakrishnan et al., in a paper \([18]\) which appeared while our work was being completed. The same authors had previously outlined how Bose-Einstein condensates in multimode cavities can lead to frustration and glassy behavior \([11,12]\). Such experiments on the multimode Dicke model would provide a unique realization of a quantum spin glass with long-range couplings, and provide a long-awaited testing ground for theories of quantum systems with strong interactions and disorder. Condensed matter realizations of quantum spin glasses have shorter-range couplings, and so do not directly map onto the theoretically solvable systems analyzed in the present paper.

Before describing our computations, we point out a key distinction between the transitions involving onset of FM\(_{SR}\) versus QSG order. In the single-mode Dicke model, all the qubits align in a common direction near the FM\(_{SR}\) phase, and can therefore be described by a collective spin of length \(N/2\) which behaves classically in the limit of large \(N\). Consequently, the dynamics near the phase transition can be described by classical equations of motion \([19]\), and the single-mode Dicke model does not realize a quantum phase transition in the conventional sense of condensed matter physics. In contrast, we will argue here that the onset of QSG order in the multimode Dicke model has non-trivial quantum fluctuations even in the limit of large \(N\), and the critical properties cannot be described by an effective classical model. Experimental studies are therefore of great interest.

Model. The Hamiltonian of the multimode Dicke model is

\[
H = \sum_{i=1}^{M} \omega_i a_i^\dagger a_i + \frac{\Delta}{4} \sum_{i=1}^{N} \sigma_i^z + \sum_{i=1}^{N} \sum_{l=1}^{M} g_{il} (a_i + a_i^\dagger) \sigma_i^x .
\] (1)

This describes \(N\) two-level atomic qubits with level splitting \(\Delta/2\) and \(M\) photon modes with frequencies \(\omega_i\) coupled by an atom-photon coupling \(g_{il}\) which depends on the photon \((i)\) and atom \((l)\) number. \(a_i^\dagger, a_i\) are bosonic creation and annihilation operators, respectively, fulfilling canonical commutation relations. \(\sigma_i^x, \sigma_i^z\) are spin-1/2 operators with Pauli matrix representation. As explained in detail in Refs. \([17,18]\), the two states of the Ising spin in Eq. \((1)\) map onto two different ground-state sublevels, \(|1\rangle\) and \(|0\rangle\), of three-level \(\Lambda\) atoms. \(|1\rangle\) and \(|0\rangle\) are indirectly coupled through a pair of Raman transitions to an excited state \(|e\rangle\) which are driven by the classical...
field of a pair of external lasers. Upon adiabatic elimination of $|e\rangle$, one obtains Eq. (1) with $\sigma_i^\alpha = |1\rangle\langle 1| \delta |0\rangle\langle 0| \delta$ and $\sigma_i^\alpha = |1\rangle\langle 0| + |0\rangle\langle 1|$. The parameters $\omega_i$, $\Delta_i$, and $g_{\ell}\delta$ can be controlled through laser frequencies and intensities. This tunability enables access to the strong-coupling Dicke regime. A dispersive shift of the cavity frequencies $\sim a_i^\dagger a_j^\dagger \sigma_i^\alpha$ does not modify our results significantly, and so will be set to zero for simplicity. A simple choice for a spatially varying atom-photon coupling is $g_{\ell}\delta = g \cos(k_x x_\ell)$ with $k_x$ the wavevector of the photon mode, and $x_\ell$ the coordinate of atom $\ell$.

In the single-mode, large photon wavelength case, we have $M = 1$, $\omega_i = \omega_0$, and $g_{\ell}\delta = g / \sqrt{N}$ and the model can be solved exactly in the $N \rightarrow \infty$ limit [5][6]. At zero temperature, there is a continuous phase transition between a paramagnetic phase (PM) and a superradiant ferromagnetic phase (FMSR) at $g = g_c = \sqrt[8]{\Delta \omega_0}/8$ at which the Ising symmetry $(a, \sigma_i) \rightarrow (-a, -\sigma_i)$, is spontaneously broken.

For the multimode Dicke model, it is useful to integrate out the photon degrees of freedom in a path-integral representation. Then the qubits are described by a Hamiltonian similar to the Ising model in a transverse field,

$$H_{\text{eff}} = \frac{\Delta}{4} \sum_{i=1}^N \sigma_i^z - \frac{1}{2} \sum_{m} g_{\ell m} \omega_{m} \sigma_i^x,$$

where the line represents a disorder average, and $\delta J_{\ell m}$ is the variation from the mean value. We have assumed couplings between different sites are uncorrelated, and this will allow an exact solution in the $N \rightarrow \infty$ limit, modulo an innocuous softening of the fixed length constraint on the Ising variable $\sigma_i^x$. We will allow arbitrary frequency dependencies in $J_0(\Omega)$ and $K(\Omega, \Omega')$. The factors of $N$ ensure an interesting $N \rightarrow \infty$ limit [23]. Especially for finite $M$, one could also use the methods of Ref. [20] to extend our analysis to models in which the $g_{\ell\delta}$ rather than the $J_{\ell m}(\Omega)$ are taken as independent random variables. However, as long as the photon modes can be chosen so that the $J_{\ell m}(\Omega)$ vary in sign and magnitude, our analysis should remain qualitatively correct also for smaller values of $M$.

Key results. We will show below that, in the limit of large atom number $N$, the results depend only upon $J_0(\Omega) = 0$ and $K(\Omega, -\Omega)$. Here, we will display the phase diagram and spectral response functions for the simple choices $J_0(0) = 2g^2/\omega_0$ and $K(\Omega, -\Omega) = J^2(\Omega)$ with

$$J(\Omega) = 2r^2 \omega_0/(\Omega^2 + \omega_0^2).$$

In Fig. [1] we depict the ground state phase diagram; a related phase diagram in a condensed matter context was obtained in Ref. [24]. All phase transitions are continuous and the respective phase boundaries merge in a bicritical point at $(t_{bc}^2 = 0.086, \ v_{bc}^2 = 1.05)$. The intersection of the PM-FMSR phase boundary with the vertical axis at $t^2 = 0$ corresponds to the phase transition in the single mode Dicke model without disorder [8][17]. In this case, a number of analytical results can be obtained from Eq.
FIG. 2: (Color online) rf spectral response function of the atomic qubits in the FMSR phase for various photon frequencies and \( r^2 = 0.025 \), \( g^2 = 0.2 \), \( \Delta = 1 \). \( \Omega \) is a real measurement frequency. The red arrow at \( \Omega = 0 \) illustrates the delta function contribution with weight \( q \sim g^2 \) from Eqs. (12–13). The value of the gap is given above Eq. (13). For the Dicke model without disorder \( (r^2 = 0) \), the spectral function following from Eq. (6) consists of nothing but two delta functions: the red arrow at \( \Omega = 0 \) and the grey arrow at \( \Omega = g\sqrt{2\Delta/\omega_0} \) (plotted for \( \omega_0 = 1.015 \)).

present across the phase transition from the FMSR phase to the PM phase. Thus all the low energy fluctuations in the critical theory for this transition are restricted to the zero frequency delta function, which can be described in classical theory for the spins: this is the reason this transition is more properly considered as a classical phase transition.

For a sufficiently large value of \( r^2 \), the system undergoes a quantum phase transition to the QSG ground state. In contrast to the PM-FMSR transition, at the QSG transition, and in the entire QSG phase, there is spectral weight at a continuum of frequencies reaching zero (see Fig. 3). Thus the onset of QSG order from the PM phase is a genuine quantum phase transition, whose universality class was described in Ref. [22].

The PM phase is clearly delineated from both, the QSG and the FMSR phases: the PM phase has a gapped spectral response and no superradiant photon condensates. We also note that in all phases, while the spectral function has a universal form at low frequencies, its high frequency behavior is strongly dependent upon the forms of the spins: this is the reason this transition is more properly considered as a classical phase transition.

Experimental signatures. The rf spectral response function of the atomic qubits presented in Figs. 2, 3 should be observable via radiofrequency spectroscopy [25, 26].

Measuring the spectrum of photons leaving the cavity through its imperfect mirrors at loss rate \( \kappa \) allows for an in-situ measurement of our phase diagram, Fig. 1. Our prediction for the spectrum of intra-cavity photons, Eq. (7), can be related to the extra-cavity photons via the input-output formalism [17, 27, 28]. For this case of a dissipative Dicke model, we note a similarity of the decay effects to those in theories of metallic spin glasses [29], in which the spin qubits are coupled to a “reservoir” of continuum spin excitations near the Fermi surface. This coupling leads to a damping term in the dynamics of each spin, but does not significantly modify the spin-spin interactions responsible for the spin glass phase.
Similarly, for the dissipative Dicke model, decay into photons outside the cavity will introduce various damping terms e.g. a $\kappa N$ term in the denominator of Eq. 3. As in the previous analyses [29], we expect that the quantum spin glass transition will survive in the presence of damping, although there will be some changes to the critical properties [30].

As in other glasses, we expect slow relaxational dynamics, along with memory and aging effects in the QSG phase which should be observable via local spin addressing protocols and measuring the spin relaxation time scale [18].

**Conclusion.** Observations of these effects in quantum optical systems would be remarkable. Moreover, the spin glass physics is driven by long-range interactions, and this makes the theoretical models analytically tractable. We therefore have prospects for a quantitative confrontation between theory and experiment in a glassy regime, something which has eluded other experimental realizations of spin glasses.

**Details of the calculation.** As discussed in Refs. [21][22], each Ising qubit, with on-site gap $\Delta/2$, is conveniently represented by fluctuations of a non-linear oscillator $\phi_i(t)$ ($\tau$ is imaginary time) which obeys a unit-length constraint. Their action at temperature $T$ is then

$$S_0[\phi, \lambda] = \frac{1}{2\Delta} \sum_{i=1}^{N} \int_{0}^{1/T} dt \left( \partial_t \phi_i(t)^2 + i \lambda_t (\phi_i(t) - 1) \right)$$

where $\tau$ is imaginary time, and the $\lambda_t$ are Lagrange multipliers which impose the constraints. The only approximation of this paper is to replace the $\lambda_t$ by their saddle-point value, $i \lambda_t = \lambda$, and to ignore their fluctuations. For decoupled oscillators, this saddle-point value is $\lambda = \Delta^2/4$, the $\phi$ susceptibility is $\Delta/(\Delta^2 + \Delta^2/4)$, and the resulting gap, $\Delta/2$, has been matched to that of the Ising spin.

The interactions between the qubits are accounted for as before [21]: we introduce replicas $a = 1, \ldots, n$, average over the $J_{ab}$ using Eq. 4, decouple the resulting two-$\phi$ coupling by Hubbard-Stratonovich transformation using a ferromagnetic order parameter $\Psi^a(\Omega)$, and the four coupling by the bilocal field $Q^{ab}(\Omega, \Omega')$ [22] (the $\Omega$ are Matsubara frequencies). The complete action is

$$S = \sum_a S_0[\phi^a, \lambda^a] + T \sum_{a, \Omega} J_0(\Omega) \left[ \frac{N}{2} |\Psi^a(\Omega)|^2 - V^a(\Omega) \right]$$

$$- \frac{1}{2} \sum_{a, \Omega, \Omega'} \left[ \frac{N}{2} (Q^{ab}(\Omega, \Omega'))^2 - Q^{ab}(-\Omega, -\Omega') \sum_{i=1}^{N} \phi_i^a(\Omega) \phi_i^b(\Omega') \right].$$

Now we perform the Gaussian integral over the $\phi$: the resulting action has a prefactor of $N$, and so can be replaced by its saddle-point value. By time-translational invariance, the saddle-point values of the fields can only have the following frequency dependence

$$\Psi^a(\Omega) = (\delta_{t,0}/T) \psi$$

$$Q^{ab}(\Omega, \Omega') = (\delta_{t,0}/T) \left[ \chi(\Omega) \delta^{ab} + (\delta_{t,0}/T) q \right],$$

and we take $t^a = \lambda$. We have assumed replica symmetry for the Edwards-Anderson order parameter $q$ because our interest will be limited here to $T = 0$ where there is no replica symmetry breaking [22]. Now the values of the ferromagnetic moment $\psi$, the spin susceptibility $\chi(\Omega)$, $q$, and $\lambda$ have to be determined by optimizing the free energy. The latter is obtained by inserting Eq. (10) in Eq. (9); after taking the replica limit $n \to 0$, we have the free energy per site

$$F = \frac{J_0(0)\psi^2}{2} + \frac{T}{4} \sum_{\Omega} \left[ K(\Omega, -\Omega)(\chi(\Omega))^2 + \frac{1}{2} K(0, 0)\chi(\Omega)q \right]$$

$$+ \frac{T}{2} \sum_{\Omega} \ln \left( \frac{\Omega^2 + \lambda}{\Delta} - K(\Omega, -\Omega)\chi(\Omega) \right) - \frac{\lambda}{2\Delta}$$

$$- \frac{1}{2} \left[ K(0, 0)q + J_0(0)\psi^2 \right].$$

Note that this free energy depends only upon $J_0(0)$ and $K(\Omega, -\Omega)$, as claimed earlier. Our results described in Eq. (6) and Figs. [13] are derived from a set of coupled saddle-point equations obtained from varying Eq. (11) with respect to $\chi(\Omega)$, $q$, $\psi$, and $\lambda$ for every $\Omega$. Subsequently we let $T \to 0$.

For the choices for $K(\Omega, -\Omega)$ and $J_0(0)$ of Eq. (5), the rf spectral response function of the atomic qubits plotted in figures [24] is given by the expression:

$$- \text{Im} \left[ Q^{nn}(i\Omega) \to \Omega \to i\Omega_0) \right] = \frac{[\omega_0^2 - \Omega^2]}{8\Delta^4\omega_0^2} \left[ 16\Delta^2 t^2 \chi(\Omega)^2 \right]$$

$$+ q 2\pi\delta(\Omega).$$

The first term is non-zero only for frequencies $\Omega$ so that the expression underneath the square-root is positive. The value of the Lagrange multiplier in the FM is pinned to $J_{a\beta} = \Delta(\delta_{a,0}(0) + K(0, 0)/J_0(0))$. The value of the gap in Fig. 2 is

$$\sqrt{\frac{1}{2} \left( \lambda_{\text{FM}} + \omega_0^2 \right)} = \sqrt{16\Delta^2 t^2 \chi(\Omega)^2},$$

which is then

$$\frac{1}{2} \left( \lambda_{\text{FM}} + \omega_0^2 \right) \left( \lambda_{\text{FM}} - \omega_0^2 \right)^2. \right.$$

This expression equates to zero in the gapless QSG phase shown in Fig. [3] where $\lambda_{\text{QSG}} = 2\Delta \sqrt{K(0, 0)}$. This gap vanishes logarithmically faster than $(t^2 - t_{\text{c}}^2)$ when approaching the QSG phase boundary due to the square-root behavior of the spectral weight [21][31].

The fermionic moment obtains as

$$\psi^2 = \frac{J_0(0) - K(0, 0)}{J_0(0)} \left[ 1 - \int_{-\infty}^{\infty} d\Omega \frac{2\pi}{\lambda_{\text{FM}} - \lambda_{\text{QSG}}} \chi(\Omega) \right] \chi(\Omega) \bigg|_{\lambda=\lambda_{\text{FM}}}.$$
